Foreword

While there is no avowed tendency to "nationalism" in science, it is inevitable that any scientist will give more attention and, hence, more apparent importance to what is being done in his own country. Such a tendency has always been known to be responsible for overemphasis on the laboratory from which emanates an author's or editor's own work. This is, perhaps, an unavoidable tendency, inherent in the nature of things, but it is pernicious because it detracts from an essential attribute of science, its universality. The geographic and, to some extent, also the cultural detachment of the great continent to the south of us has yielded an unique fruit in this remarkable treatise on physiology. It is the product of a group of men who not only are fruitful investigators but who, working where science has not hitherto been intensively cultivated, have felt themselves forced to study conscientiously the literature in mammalian physiology produced throughout the world. They have thus the perspective requisite for a balanced account.

The group has furthermore led an ideal intellectual life with daily or at least frequent intercommunication. It has been led by a great individual, Bernardo A. Houssay, whose capacity to break new ground has been adequately acknowledged by a Nobel award. Those who had watched the initiation of Professor Houssay's career and the remarkable School which he had set up in that great capital, Buenos Aires, were not surprised by his brilliant Dunham Lectures at Harvard University some years ago, but it is perhaps safe to say that the Dunham Lectures first introduced this scholar and his pupils to his North American confreres.

The group effort just mentioned has conferred upon this treatise a remarkable unity, a unity otherwise given a treatise only by a single individual, and it is well known that it is no longer possible for an individual to cover the whole field of a given science. Furthermore, the English version of the treatise has been provided by one of its authors, Juan Lewis, and that has itself aided the uniformity and harmony of the book.

While the sections on circulatory physiology, under the able auspices of Orías, and renal physiology, under Braun-Menéndez, could be compared advantageously with any textual treatments of these themes, it is inevitable that the outstanding excellence of this treatise will be considered its treatment of the field of endocrine physiology, a field of enormous present-day importance, in which almost daily advances are being made. All North American colleagues of these Argentine scientists now welcome warmly this signal accomplishment of the group.

Preface

This book has been written for medical students and for doctors of medicine who wish to study the fundamental principles of modern physiology. It has been written for students who have no knowledge of pathology, but who must acquire the physiological basis necessary for the study of disease and the practice of medicine. A book to be used in medical education cannot be merely a textbook of applied medical physiology; therefore the facts of human physiology have been given preferential, but not exclusive, consideration. Human physiology is better understood in the light of general and comparative physiology, and a living organism is more completely known when there is some knowledge of other species. Many advances in human physiology have originated in studies on isolated cells, on yeasts, and on the lower animals.

Physiology is a science that studies the phenomena occurring in living organisms and endeavors to establish their laws. It is that part of biological science which studies the functions of living organisms in health and disease. The knowledge of physiology is indispensable in medicine because the same general laws apply to normal and to pathologic conditions of life; disease is simply the modification or deviation of normal function and cannot be understood without previous knowledge of the normal state.

Physiology as a science is not dependent on medicine, and as such it should be studied for its own sake, without being limited to its medical, veterinary, or zootechnical applications. Even in a medical school, the study of physiology should not be reduced to problems of human physiology and its medical applications. Undoubtedly, however, human medicine has been the most powerful stimulus for the study of physiology, and even now in several countries it is taught only in medical schools.

An outstanding feature of modern medicine is its physiological foundation. Medicine has a threefold purpose: to preserve health, to prevent disease, and to cure disease. The doctor in the first place must know how to preserve and improve health, which is the normal condition of man's life, whereas illness attacks him only during short periods. The advancement of physiology and experimental medicine has been instrumental in the lengthening of life and in ever greater efficiency in the prevention and treatment of disease.

Physiological discoveries sooner or later always find useful applications in medicine and in hygiene, but they must first become familiar to the medical man. Unfortunately, many years often pass by before these applications enter into current medical practice. A solid grounding in physiology and in the experimental method, from the very beginning of medical education, will do much to remedy this regrettable state of affairs.

The desire to obtain the benefit of applied science must not make one forget that an exclusive interest in that which is immediately practical ends in a narrow rut of mediocrity. The most useful discoveries in medicine have been the consequence of disinterested research, not directed toward any definite application. Excessive preoccupation with practical results leads to shortsightedness and diminishes the fertility and scope of research and knowledge. There is no pure science; there is only science and its applications, which may be evident immediately or may take some time to develop. It is a common belief that many physiological facts are of only academic interest and have little or no practical value. This serious misconception should be corrected; every method of diagnosis and treatment now in use is the outcome of disinterested scientific research, and no one can say that knowledge that is apparently useless today will not have some application tomorrow that may be of great value.

Medical students can be taught only a small part of all that is known. The choice of what is most formative and useful will best be made by those with a wide knowledge of the science to be taught and with personal experience in its methods and techniques. Such competency can be achieved only after long and arduous work in the laboratory with complete dedication to the task.

A textbook of physiology for medical students and doctors must strike a balance between widely differing requirements. It must expound ideas taken from several sciences applied in physiology; it must explain the general principles of physiology and the functions of the different organs and systems, as well as their correlations; finally, it must integrate information obtained by the clinical and experimental study of altered function. A student can assimilate only a limited amount of knowledge in the time given to physiology in a well-balanced medical curriculum. This requires wise discrimination between the little that can be taught and the far wider field that must be left out. It is far better to have precise knowledge of fundamental principles than vague ideas about a great number of facts.

The facts of human physiology should be used in preference to physiological facts on other species for the illustration of general principles, thus satisfying the need for applied knowledge and at the same time linking it up with medicine and surgery. The tendency to separate them fostered by the inevitable separation between the clinic and the laboratory will thus be counteracted. It will be of great advantage for the education of the future physicians, and for the advancement of medicine and of physiology, if the development of as many contacts as possible is stimulated by the study of problems common to physiology and medicine.

Many problems can be solved only by animal experimentation, and most of the discoveries afterward usefully applied in man were first made by this method. Nevertheless research in human physiology has the advantage that its results can be applied immediately to man and that the subjects can give reasonable and conscious collaboration, which cannot be obtained from animals.

The study of pathologic conditions is also important, because knowledge of disease or altered function is useful for the understanding of normal function. Diseases can be considered as natural experiments, some of which have given valuable information not obtained from laboratory experiments. Clinical physiologists contribute daily to the advancement of physiology, and reciprocally a profound knowledge of physiology is indispensable for the making of original discoveries in clinical medicine and for efficiency in the practice of medicine. In the teaching of physiology, demonstrations in healthy subjects and a variety of clinical cases become more useful every day.

The student should never lose sight of the fact that it is only for didactic reasons that the different systems and organs are considered separately, as if they could be taken apart from the rest of the organism. This separation is completely artificial, as the whole organism is an indivisible anatomic and functional unit.

Physiology is in a constant process of evolution and advancement; a textbook should reflect this active life and not give the impression of a catalogue of completed and unchangeable statements. The reader's interest should be awakened by this progressive evolution, and the wish should be born in him to follow this continuous increase in knowledge and, if possible, to make personal contributions to it.

Science in general, and physiology in particular, can be taught properly only by intense, practical, and individual teaching—a fact recognized in all advanced centers of medical education. A book cannot be a substitute for this kind of teaching; it can be no more than a useful guide. The practical and rational study of physiology develops a scientific attitude of mind; namely, the capacity to find truth and to recognize error, and the habit of rigorous demonstration instead of dogmatic affirmation of imaginative statements that dazzle the simple-minded.

Physiology is nourished by experimental research, which is the permanent search for truth by adequate and precise methods. It is conscientious and continuous searching and researching so as to increase and perfect knowledge. In former times the only precise medical science was that of normal anatomy; later that of pathologic anatomy was added; at a still later date bacteriology was preeminent; today we are in the era of physiology, which has rejuvenated these sciences and given fresh vigor to them and to medicine in general.

In this book, statements will be supported by adequate proof as far as possible, so as to create the habit of critical appreciation. Unfortunately, for reasons of space it is not possible to do this in all cases, but it must be understood that these demonstrations exist and are available in more specialized books or in the original papers quoted in the bibliographic references. The only way of avoiding the intellectual vice of unreasoned acceptance of unsupported statements, when these are presented in an attractive form, is a practical and individual education in the scientific method. For such an education, no textbook can be a substitute.

Students do not always have sufficient training in the basic sciences of biology, physics, and chemistry. In other cases, their knowledge has been forgotten. It is therefore sometimes necessary to recall certain facts that ought to be familiar. Other indispensable information in anatomy, histology, embryology, biochemistry, and biophysics is omitted because it is considered as known or can be easily found in the appropriate textbooks. A few subjects of great importance are treated somewhat summarily, *e.g.*, nutrition and growth in childhood, and pregnancy and parturition. In the course of medical studies, these will be discussed in greater detail in pediatrics, obstetrics, etc. Certain information considered of secondary or mainly clinical interest, or debatable questions, or the description of methods, is included in smaller print. At the foot of the page reference is made to a few classic papers and to others of recent date that describe work of importance. At the end of each chapter there is a short list of books and papers which will help those who wish to make a deeper study of the subject in question.

Information included in this book has been obtained from sources in all countries and languages, and although sometimes the work done by the authors' group is given in greater detail, an effort has been made to keep this within reasonable bounds. The authors have been engaged for many years exclusively in teaching and research, and although they give their personal views and experience of the different problems, they have tried to render a balanced account covering the whole field of physiology. The book has been written in difficult circumstances, which have caused some otherwise avoidable defects. Also it is not easy to choose wisely and to present adequate knowledge in a field that is constantly developing over an ever wider area, extending to several allied sciences, and in which information must be kept up to date.

This book was written originally to satisfy the need of South American students. Later, French, Portuguese, and English editions were published. The authors have revised the text of each new edition; they have made many corrections, some of the chapters have been almost completely rewritten, and every effort has been made to keep the book up to date.

The authors will be grateful for constructive criticism and suggestions that may help to improve the book and make it a more efficient stimulus and guide for students, thus fulfilling the purpose with which it was written.

BERNARDO A. HOUSSAY

STANDARD UNITS

Mass: The unit is the gram (gram mass, gm.); 1 gm. is the mass of 1 ml. of water at 4°C.; it is the one-thousandth part of the international standard kilogram, made of platinum and iridium, which is kept in Paris.

Time: The unit is the second (sec.); 1 sec. is the sixtieth part of 1 min., which is the sixtieth part of 1 hr.; 1 hr. is the twenty-fourth part of the average solar day; *i.e.*, the average duration of the days in the solar year (86,400 sec.).

Length: The unit is the centimeter (cm.); 1 cm. is the hundredth part of the standard meter, which is the distance between two lines on a platinum bar kept in Paris; it is approximately one ten-millionth part of a quadrant of a meridian of the earth.

Velocity: The unit is the centimeter per second (cm./sec.).

Acceleration: The unit is the centimeter per second per second (cm./sec.^{2}).

Force: The CGS[1] unit is the dyne; 1 dyne is the force that, acting on a mass of 1 gm. for 1 sec., imparts to it a velocity of 1 cm./sec., *i.e.*, causes an acceleration of 1 cm./sec.^{2} The unit of gravity is the gram weight; 1 gram weight is the force with which the earth attracts 1 gram mass. It is equal to 981 (980.665) dynes and imparts to 1 gram mass an acceleration of 981 cm./sec.^{2} It varies in different places.

Work: The CGS unit is the erg; 1 erg is the force of 1 dyne acting through a distance of 1 cm.; *i.e.*, 1 erg = 1 dyne $\times$ 1 cm. = 23.8 $\times$ 10^{-9} cal. = 10.19 $\times$ 10^{-4} gm.-cm. One joule = 10^7 ergs = 0.23885 cal. The gravitational unit is the gram-centimeter; 1 gm.-cm. = 981 ergs = 23.43 $\times$ 10^{-6} cal., *i.e.*, 23.43 microcalories. The kilogram-meter (kg.-m.) is the most commonly used unit; it is the amount of work spent in raising a mass of 1 kg. to a height of 1 m. It is equal to 9.81 joules.

[1] Centimeter-gram-second, or metric, system of measurement.

Power: The CGS unit is the erg per second. One watt = 10^7 ergs/sec. = 1 joule per second. One kilowatt (kw.) = 10^3 watts = 10^{10} ergs/sec. The gravitational unit is the gram-centimeter per second. The metric horsepower is 75 kg.-m./sec. = 0.736 kw. The English horsepower (hp.) is 550 foot-pounds per second = 0.746 kw.

Heat: The unit is the calorie (cal.) or small calorie; 1 cal. is the amount of heat required to raise the temperature of 1 gm. of distilled water 1 degree centigrade (from 14.5 to 15.5°C.); it is equivalent to 4.185 $\times$ 10^{-7} erg = 0.4266 kg.-m. = 4.185 joules. One kilogram-calorie (kg.-cal.) or large calorie (Cal.) is 1,000 cal. = 426.6 kg.-m. = 4,1868 joules.

Temperature: The unit is the degree centigrade (°C.); 1 degree centigrade is the one-hundredth part of the difference in the temperature of melting ice and water boiling at a pressure of 760 mm. Hg. Zero in the centigrade scale corresponds to 273° (273.15°) in the scale of absolute temperature (T or K).

Mole is the molecular weight of a substance in grams = 6.02 $\times$ 10^{23} molecules (Avogadro's number). One millimole = 10^{-3} gram molecular weight. One micromole = 10^{-6} gram molecular weight.

Molar solution contains 1 mole or the molecular weight of the solute in grams in 1 liter of solution. It exerts an osmotic pressure of 22.4 atmospheres at 0°C., and its freezing point is —1.86°C. if the solute is not dissociated.

ABBREVIATIONS AND SYMBOLS FOR STANDARD UNITS

SECTION ONE

The Internal Environment and the Blood

CHAPTER 1

The Internal Environment and the Blood

THE INTERNAL ENVIRONMENT

The body fluids. Water constitutes about two-thirds of the body of an adult man. It can be said that the organism is made up of water in which micellae, molecules, and ions are dispersed. The physical and chemical reactions of colloidal and true solutions are therefore of fundamental importance in living organisms.

The body fluids are distributed in three compartments. One is within the cells, the *intracellular fluid;* the other two, outside the cells and forming the *extracellular fluid*, are the *interstitial fluid* and the *blood plasma*. Between these last two compartments the exchange of diffusible substances is easy and continuous, so they have a very similar content of water and salts.

Fluid blood is made up of a liquid, the blood plasma, in which cells (erythrocytes, leukocytes, and platelets) and minute particles (hemokonia or chylomicrons) are suspended. When blood coagulates, it first becomes solid and then a fluid oozes out, which is called the serum.

The internal environment. Multicellular organisms are surrounded by an external environment—air or water—but their cells live in a fluid environment which Claude Bernard in 1878 named the "*milieu intérieur*" (internal environment). This *milieu* is formed by the extracellular fluids, *i.e.*, by (*a*) the interstitial or tissue fluids, which bathe the cells and circulate slowly; (*b*) the lymph contained in the lymphatic vessels, which goes from the tissues to the blood; (*c*) the blood plasma, which circulates rapidly. The cerebrospinal fluid, the aqueous humor of the eye, and the fluid in the pleural and peritoneal cavities, the joints, and the synovial sheaths are particular forms of interstitial fluid.

The blood is the part of the *milieu intérieur* that circulates rapidly within a closed system of vessels. An outstanding feature of the blood is the constancy of its chemical composition and physical properties, thus assuring constant conditions for the functioning of the cells. The blood is being continuously renewed by incoming and outgoing cells and substances; nevertheless the variations in its composition fluctuate within a narrow margin and are rapidly corrected. The functions of the organism are regulated so as to maintain the stability of the internal environment, a physiological fact of great importance which Claude Bernard first pointed out and called the "fixity of the *milieu intérieur*." The concept was developed by Cannon, who coined the term "homeostasis" to signify those steady states maintained by coordinated complex physiologic reactions.

Therefore, on the one hand the blood assures constant conditions to the cells, and on the other the organism maintains the chemical, physical, and morphologic constancy of the blood. According to Claude Bernard, the fixity of the internal environment is the necessary condition for the free and independent life of higher organisms.

THE BLOOD

Blood consists of a fluid in which there are free cells—the red cells, or erythrocytes; the white cells, or leukocytes; and the platelets. It is also a dispersion of micellae, molecules, and ions in water, and therefore has the properties of colloidal and true solutions.

The relative volumes of erythrocytes and plasma. The volume of cells in 100 cc. of

tion) with the plasma above. The specific gravity of the blood is conditioned mainly by the number of red blood cells; it is greater in man, 1.059 (1.052 to 1.063), than in woman, 1.056 (1.050 to 1.058). The specific gravity of plasma and of serum is principally due to the
FIG. 2. Demonstration of osmotic pressure.

protein concentration and is therefore used to measure approximately the protein content.[1] As the method is simple and rapid, it is frequently used to follow variations in plasma-protein concentration in cases of shock, burns, etc.

The specific gravity of whole blood increases and decreases with the erythrocyte concentration. It is possible to calculate the hemoglobin concentration of blood by measuring the specific gravities of whole blood and of plasma.[2]

The specific gravity of the blood plasma or serum can be determined by weighing a standard quantity in a pyknometer. Another method consists in comparing the specific gravity of a drop of blood with that of solutions of known specific gravity. Several techniques have been proposed; that of Phillips and Van Slyke[3] has the advantage of simplicity. A drop of blood is introduced into each of a series of tubes containing different concentrations of copper sulfate of known specific gravity. The drop is surrounded by a thin coat of coagulated protein, and it falls if its specific gravity is higher than that of the solution but rises if it is lower. If the specific gravity of the blood is the same as that of the solution, the drop remains in equilibrium after 10 to 15 sec. Three or four drops of blood are sufficient, and the whole procedure can be completed in 1 min.

[2] *Ibid.*, p. 349.

[3] PHILLIPS, R. A., D. D. VAN SLYKE, *et al.*, *J. Biol. Chem.*, **183**, 305, 1950.

Viscosity. A fluid in movement has the property of viscosity because of internal friction between its constituent particles. The viscosity of whole blood is strictly dependent on the red cell count. In man the relative viscosity is on an average 4.7 (4.3 to 5.3) and in woman 4.4 (3.9 to 4.9), taking that of distilled water as unity, and measuring it in the Hess viscosimeter.[1] The viscosity of plasma or serum is lower than that of whole blood; measured in Ostwald's viscosimeter, it is 1.6 to 2.2 for serum, and about 20 per cent higher for plasma. The viscosity of plasma is in direct proportion to the total protein concentration, and especially to the concentration of serum globulin, which has large, long, and asymmetric molecules. In hypothyroidism (thyroid insufficiency) there is an increase in blood globulins, and therefore in the viscosity of the plasma; while in hyperthyroidism (excess thyroid function) plasma globulins and viscosity diminish.

Osmotic pressure. This is pressure developed by water[2] when it passes through a semipermeable membrane from a dilute solution to a concentrated solution (Fig. 2). A semipermeable membrane[3] is permeable only to water and not to the substances in the solution. Osmotic pressure can be demonstrated in the following way (Fig. 2): A solution of sugar in water is placed in a flask *B*, the bottom of which is a semipermeable membrane; the top is hermetically closed by a piston or by a stopper pierced by the tube of a manometer. The flask is submerged in a larger receptacle *A* full of water. Molecules of water will pass through the membrane in both directions, but in much greater number

[1] HESS, W. R., *Deutsch. f. klin. Med.*, **94**, 404, 1908.

[2] Only aqueous solutions are mentioned, as these are the only ones of importance in living organisms.

[3] Pfeffer used a copper ferrocyanide membrane, but others are also used, although most of them are not strictly semipermeable, as other molecules besides those of water pass through them.

from *A* to *B* than from *B* to *A*, and the piston will rise in *B* or the manometer will mark a rise in pressure. If an adequate weight is placed on the piston, the same number of molecules of water will be forced through the membrane from *B* to *A* as that passing from *A* to *B*, so the piston will remain stationary. The weight needed to keep the piston from rising is the equivalent of the hydraulic pressure developed by the osmotic pressure and therefore serves to measure it.

The substance dissolved in a solution occupies space within the solvent; therefore the concentration of water in *A* (pure water) is greater than in *B* (solution); more molecules of water will therefore bombard the semipermeable membrane on the side of *A* than on that of *B*, and more will pass through it from *A* to *B* than from *B* to *A*.

The osmotic pressure developed by a solution is equivalent to the pressure that the dissolved substance would develop if it were a gas at the same pressure and temperature. One gram molecule of any gas at 760 mm. Hg and 0°C. has a volume of 22.4 liters; compressed to a volume of 1 liter, it develops a pressure of 22.4 atmospheres at 0°C.

The gas laws can therefore be applied to solutions. Consequently, (*a*) solutions with the same osmotic pressure at the same temperature contain the same number of molecules in unit volume (Avogadro's law); (*b*) at a constant temperature the osmotic pressure is proportional to the molecular concentration (the Boyle-Mariotte law); (*c*) with a constant molecular concentration the osmotic pressure is proportional to the absolute temperature (Gay-Lussac's law); (*d*) if several substances are dissolved in the same solvent, each one develops osmotic pressure as if it were the only substance dissolved; therefore the total osmotic pressure is the sum of the partial osmotic pressures of the substances in solution (Dalton's law). These laws are valid for dilute solutions; in concentrated solutions there are other factors that limit their applicability.

Electrolytes in solution are partially dissociated into their constituent ions; the osmotic pressure of these solutions is that developed by the concentration of all the particles, molecules and ions. Thus the osmotic pressure of a molar solution of NaCl (58.5 gm. per liter) is not the same as that of a molar solution of glucose (180 gm. per liter) but almost twice as much (1.94), because the salt is almost completely dissociated into its two ions.

Osmotic pressure is usually measured by indirect methods, because they are simpler and less open to error than direct ones. Indirect methods are based on the fact that several properties of solutions are conditioned by the concentration in particles (molecules, ions, and micellae). These properties are the following: osmotic pressure, freezing point, boiling point, and evaporation pressure. The freezing point of a solution is lower than that of the pure solvent, and the depression of the freezing point is proportional to the concentration of particles in the solution. By measuring this depression, therefore, the osmotic pressure can be calculated. A molar solution (1 gram molecule per liter) freezes at −1.86°C. and has an osmotic pressure of 22.4 atmospheres at NTP (normal temperature and pressure, *i.e.*, 0°C. and 760 mm. Hg).

Solutions of the same osmotic pressure are called isotonic. Of two solutions, the one with the higher osmotic pressure is hypertonic with respect to the one with the lower osmotic pressure, and reciprocally this second one is hypotonic with respect to the first.

The osmotic pressure of whole blood is approximately the same as that of plasma or of serum. The lower marine animals have more or less the same osmotic pressure as the sea water in which they live; they are known as "poikilosmotic" because their osmotic pressure is dependent on that of the external environment. More developed species have a constant osmotic pressure; they are called "homoiosmotic" because the pressure of their blood plasma is maintained at a constant level. Human plasma freezes at −0.56°C. (−0.54 to −0.59°C.), which corresponds to a 0.3 molar solution, and an osmotic pressure of 6.7 atmospheres. Seventy-five per cent of this pressure is due to NaCl. A 0.9 per cent NaCl solution is isotonic with plasma (has the same osmotic pressure); this is known as normal saline or physiologic solution.

The osmotic pressure developed by the plasma proteins is quantitatively much less than that of other plasmatic substances, but it is of great importance (Starling). Water and crystalloids diffuse easily through the membranes of the capillaries, so they are in approximately the same concentration in the interstitial fluid as in the blood plasma. The plasma proteins, on the contrary, do not diffuse readily through the capillary membrane and, as they remain within the blood vessels, they retain water. To make

water leave the capillaries, it is necessary to apply, within the blood vessels, a hydrostatic pressure higher than the osmotic pressure of the plasma proteins.

The osmotic pressure of the plasma proteins can be measured by placing plasma, or the plasma proteins, in a small osmometer with a cellophane membrane submerged in a fluid of the same saline concentration as plasma, *e.g.*, Ringer's or Locke's solutions, or in plasma ultrafiltrate. In this case the pressure developed (colloidal osmotic or oncotic pressure) is determined by two factors: (*a*) the true osmotic pressure, *i.e.*, pressure dependent on the molecular concentration of protein; (*b*) pressure developed by hydration and consequent swelling of the protein micellae (imbibition).

Table 1. Chemical Composition of Blood, Plasma, and Erythrocytes

Constituents	*Blood*	*Plasma*	*Erythrocytes*
	Gm./100 cc.		
Water	78.0 (77–85)	90.7	66.0
Total solids	22.0 (18–23)	9.3	34.0
Organic substances	21.2	8.5	33.0

The plasma proteins develop an osmotic pressure of 25 to 35 mm. Hg. The osmotic pressure of serum albumin is much greater than that of serum globulin; therefore its capacity to retain water is also greater. This difference is due to the smaller size of the molecule of serum albumin, so that in the same weight there are more molecules (particles) of serum albumin than of serum globulin. Also the oncotic pressure of serum albumin is greater. Serum albumin accounts for 80 per cent of the total osmotic pressure developed by the plasma proteins. One gram of serum albumin retains 18 cc. of water at 22 mm. Hg, 25°C., and pH 7.4, and is equivalent in this respect to 20 cc. of citrated plasma. A solution of 25 gm. of serum albumin in 100 cc. of water can retain within the blood vessels as much water as 500 cc. of citrated plasma.[1] This fact has led to the use of plasma or serum albumin solutions in the treatment of shock produced by wounds and burns, with the object of increasing the blood volume by attracting and retaining water within the blood vessels. This has been one of the major advances in therapeutics of recent years.

When the concentration of plasma proteins or of serum albumin diminishes, water and salts easily diffuse from the capillaries because the blood pressure is much higher than the osmotic pressure of the plasma proteins. In hypoproteinemia and hypoalbuminemia the interstitial fluid increases and edema results.

Chemical Composition

The principal constituents of blood and their average concentration are given in Tables 1 and 2.

INORGANIC CONSTITUENTS

Plasma contains 90 per cent water and the erythrocytes only 65 per cent. There are also differences in the mineral composition of plasma and cells. Thus extracellular fluid, *i.e.*, plasma and interstitial fluid, has a preponderance of Cl, Na, and Ca; human erythrocytes, on the

[1] Scatchard, G., A. C. Batchelder, and A. Brown, *J. Clin. Investigation,* **23**, 458, 1944.

other hand, contain almost all the iron there is in the blood, much more K than plasma, and a little more Mg. Nevertheless the small quantities of plasmatic K and Mg are of great physiologic significance. These elements, together with Na and Ca, maintain an ionic equilibrium which is of fundamental importance in the life and function of cells.[1]

*When separation of the erythrocytes has been delayed, K in plasma rises to 20 mg. (18 to 22 mg.) per 100 ml.

Seventy-five per cent of the molecules in blood plasma are electrolytes, and of the latter three-quarters are NaCl. Na constitutes 92 per cent of the base in plasma, while K makes up almost all the base in the human erythrocyte.

Phosphorus in the blood is found in four different kinds of combination: *inorganic* (orthophosphate), and three *organic*, which are *ester phosphorus* (glycerophosphates, hexosephosphates), *lipid phosphorus* (phosphatids), and a very small amount of *nucleic acid phosphorus*. The inorganic P is less than one-tenth of the total P.

The concentration of the inorganic constituents is frequently expressed in milliequivalents per liter (mEq./liter), because the elements combine with each other in equivalent quantities. The chemical equivalent of an element in a solution is calculated by dividing the concentration in grams per liter by the atomic weight and multiplying by the chemical valence. Thus, the concentration of Ca in blood plasma is 100 mg. per liter, its atomic weight is 40.07, and it is divalent. Therefore $\frac{0.100 \times 2}{40.07} =$ 0.0049 equivalents per liter, or $0.0049 \times 1{,}000 = 4.9$ mEq./liter. There is 3.35 gm. per liter Na in blood plasma, its atomic weight is 23, and it is monovalent; therefore $\frac{3.35 \times 1}{23} = 0.1456$ equivalents per liter or 145.6 mEq./liter of Na in plasma. Concentration in milliequivalents per liter can be obtained by multiplying the concentration, in milligrams per 100 ml., by the following figures: Na, 0.431; K, 0.25; Ca, 0.5; P, 0.324; Cl, 0.284; CO_2 (volume in cubic centimeters per 100 ml.), 0.45.

The physiologic significance and variations of the inorganic constituents of blood plasma will be considered in Chap. 45, when dealing with mineral metabolism.

PLASMA PROTEINS

Amount and fractions. The total concentration of plasma proteins is about 7.0 gm. per cent (6 to 8 gm. per cent). When salts[1] are added the proteins are precipitated in the following order: fibrinogen, euglobulins, pseudoglobulins, and serum albumin. Proteins with large molecules are less stable than those with smaller molecules. Thus fibrinogen has a molecular weight of 500,000, that of the various globulins is about 150,000, and that of serum albumin is

[1] There is a mistaken idea that the mineral content of blood plasma is similar to that of sea water (Bunge, 1889; Quinton, 1897; Macallum, 1903). Blood plasma has a lower total mineral concentration than sea water, and relatively more K and less Mg and sulfate (MACALLUM, *Physiol. Rev.*, **6**, 316, 1926).

[1] Ammonium sulfate or sodium sulfate (Howe, 1921), in gradually increasing concentrations, is used. Different concentrations of alcohol at low temperature (5°C.) have been used with great advantage, because at this temperature alcohol does not alter the proteins (Cohn).

69,000 (Fig. 3). Serum albumin (the highest concentration) is 4 to 5.6 gm. per cent; globulins, 1.5 to 3 gm. per cent; and fibrinogen, 0.20 to 0.4 gm. per cent. The albumin-globulin ratio varies from 1.5 to 2. With the albumin a small quantity of glycoprotein[1] is precipitated (serum mucoid or globomucoid).

Fibrinogen is responsible for the coagulation of the blood when it changes from a hydrosol to a gel, called fibrin (see Chap. 8); it is unstable, and when plasma is heated it coagulates at 56 to 60°C., before the other proteins. Globulins are the most viscous of all the plasma proteins.

The antibodies, *i.e.*, the antitoxin activity of antitoxic serums, are found in the euglobulins; when these are precipitated and redissolved the solution is called concentrated antitoxic serum or antitoxin.[2] Serum albumin can be obtained in crystallized form; it is the plasma protein with the highest osmotic pressure.

The protein content is estimated by precipitating the proteins with salts, or coagulating them by heat or acids, and then weighing the precipitate or determining the nitrogen content. The plasma protein content can be calculated by colorimetric estimation of some amino acids. The specific gravity and the refractive index of plasma have also been used for determining the protein content. These methods are simple and quick, and for this reason are much in use for clinical purposes.

In an electric field, proteins in solution migrate toward one of the poles; this is known as electrophoresis. The velocity of migration depends on the electric charge of each particle. At an adequate pH the different proteins migrate at different velocities. By means of a photographic method developed by Tiselius (1937), it is possible to register the velocity and relative concentration of the different proteins. The order of velocity for the plasma proteins is the following: serum albumin, α globulins (α_1, α_2), β globulins (β_1, β_2), fibrinogen, and γ globulin (the latter having the lowest velocity). This method gives a more detailed analysis of the plasma proteins than does precipitation.

The relative amounts of the different proteins are the following: serum albumin, 55 per cent; α globulin, 13 per cent; β globulin, 14 per cent; γ globulin, 11 per cent; fibrinogen, 7 per cent. During the Second World War, fractionation of the plasma proteins for therapeutic use was greatly developed. Serum albumin is used in transfusion to restore the blood volume; fibrinogen, to accelerate blood clotting in wounds; γ globulin, in the prevention and treat-

[1] Mannose, galactose, and hexosamine form part of its molecule.

[2] This preparation does not contain pure antitoxin; part of the inactive substances can be eliminated by partially digesting the serum; antitoxin resists this operation and can be precipitated afterward (see Chap. 9).

ment of measles. E. Cohn[1] has directed a committee which has made numerous and important studies on the chemistry and physicochemistry of blood plasma and on its therapeutic and immunologic properties.

Functions of the plasma proteins. Plasma proteins are of great physiologic importance. A marked decrease in their concentration (hypoproteinemia) is accompanied by lesions in several organs, delay in the healing of wounds, and edema. The edema is due to accumulation of interstitial fluid, owing to the fact that water escapes from the capillaries because of the low osmotic pressure of the blood plasma. The principal functions of the plasma proteins are the following:

1. *Nutrition.* Total plasma or serum albumin given in intravenous injection is used in protein metabolism, and in the formation of plasma proteins and hemoglobin.
2. *Blood clotting.* This is due to the transformation of fibrinogen into a gel—fibrin—by the action of thrombin (see Chap. 8).
3. *Blood viscosity.* The proteins with larger and more asymmetric molecules (globulins) play a more important part than serum albumin in giving the blood a certain viscosity, which is an important factor in conditioning the work of the heart and in maintaining the blood pressure.
4. *Osmotic pressure.* Plasma proteins, owing to their osmotic pressure, are important for the retention of water within the capillaries (see page 7).
5. *Suspension stability of the erythrocytes.* This is dependent principally on fibrinogen, less on globulin, and much less on albumin concentration (see Chap. 3).
6. *Immunity.* The active principles in immune serums are precipitated by salts together with the euglobulins, more specifically with the γ globulins and partly with β globulin separated by electrophoresis.
7. *Acid-base equilibrium.* A protein behaves as a weak acid when in solution in a medium that is alkaline with respect to the isoelectric point of the protein; in an acid medium it behaves as a weak alkali.

The formation of plasma proteins. Plasma proteins are being continuously formed and destroyed. They do not constitute an inert store, but are in a constantly changing dynamic equilibrium. There is a small reserve of plasma proteins in the tissue, and they can be rapidly regenerated.

Plasmapheresis has been used in the study of the regeneration of plasma proteins. The animal is bled and the erythrocytes, suspended in saline solution, are reinjected, thus removing the plasma proteins. When the plasma protein concentration falls below 1 or 2 per cent, severe shock results. By provoking a less marked depletion, practicing plasmapheresis once a week, it is possible to demonstrate that several foodstuffs have a qualitative and quantitative influence on the formation of plasma proteins (Whipple).[1] Ingestion of amino acids increases the formation of plasma proteins. An inadequate diet can be the cause of hypoproteinemia, and in this case there is a deficient regeneration of plasma proteins after hemorrhage. Infection has a similar effect.

Plasma proteins and hemoglobin can be formed when the following substances are injected intravenously: plasma; serum; the product of digestion of plasma or serum; the product of advanced digestion of hemoglobin or of casein; or the amino acids indispensable for nitrogen equilibrium (Elman, Whipple).

Fibrinogen is rapidly regenerated; it is almost completely restored in 6 to 24 hr., but not if the liver has been removed, as it is formed in this organ.[2] There is a small extrahepatic store of fibrinogen. The regeneration of other plasma proteins is considerably delayed after hepatectomy, so probably the liver plays an important part in their formation.

There is a lower concentration of proteins and of serum albumin in children than in adults. During pregnancy albumin decreases, and fibrinogen and in a lesser degree globulins increase.

In many acute infectious diseases, fibrinogen increases; in several chronic infectious diseases and in the course of immunization, globulins increase. In nephrosis albumin is lost in the urine, so its concen-

tration in plasma diminishes and consequently edema is produced. The thyroid gland has a marked influence on the plasma globulins; α globulin increases in hypothyroidism (thyroid insufficiency) and decreases in hyperthyroidism (excess thyroid function).

NONPROTEIN NITROGEN

After the plasma proteins have been completely removed, the plasma contains only crystalloid nitrogenous compounds. The nitrogen of these substances is known as nonprotein nitrogen; its concentration is from 25 to 35 mg. per 100 cc.[1] (see Table 1).

The plasma proteins are usually removed by precipitation, but they can also be separated by ultrafiltration. Urea is the principal nonprotein nitrogenous substance; about one-half of the total nonprotein nitrogen is in the form of urea; then in decreasing order of concentration come the amino acids, uric acid, creatinine (usually determined as creatine),[2] and finally an important fraction called the undetermined nitrogen (Table 1).

Three factors have an influence on the nonprotein nitrogen: (*a*) *deficient renal excretion;* (*b*) *excess production;* (*c*) *increased fixation in the tissues.* In renal insufficiency nonprotein nitrogen accumulates in the blood, because of deficient excretion; the determination of its concentration in blood, or of urea or creatinine concentration, is used in the diagnosis and prognosis of renal disease. Nonprotein nitrogen also increases in the following cases: when there is severe dehydration, shock, acute adrenal insufficiency, hemorrhage into the digestive tract; after the ingestion of hemoglobin; and in some acute infectious diseases. In many of these cases there seems to be an excess production of nonprotein nitrogenous compounds. A decrease in nonprotein nitrogen concentration is observed only occasionally at the end of pregnancy, and more markedly a few hours after injecting the growth-promoting extract of the anterior hypophysis. In both these cases it is supposed that this decrease is due to increased fixation of nitrogenous substances by growing tissues.

[1] Folin, O., *Physiol. Rev.*, **2**, 460, 1922.

[2] Only about 80 per cent of what is estimated colorimetrically in the plasma as creatine is really creatine, and from 30 to 40 per cent of what is estimated in the erythrocytes (Beard).

OTHER CONSTITUENTS

Blood contains other inorganic substances beside those already mentioned, and several organic substances, such as glucose, lipids, cholesterol, enzymes, hormones (internal secretions), and antibodies (immune substances). Blood also has several gases in solution or in combination. All these constituents will be studied in following chapters. The acid-base equilibrium of the blood will be considered in the discussion of respiration (see Chap. 29).

CHAPTER 2

The Blood Volume

THE RED CELL COUNT and hematocrit readings give the concentration of erythrocytes and the percentage of plasma, but they give no information as to the total quantity of red cells or plasma. Knowledge of the total amount of blood, plasma, and erythrocytes is of great importance for the understanding of the physiology and pathology of the blood, the circulation, and respiration.

METHODS FOR THE ESTIMATION OF BLOOD VOLUME

The total amount of blood, plasma, and erythrocytes can be measured by direct and indirect methods. The data obtained could be expressed in weight, but it is usual to give them in volume and to speak of total blood volume, plasma volume, and erythrocyte volume.

DIRECT METHOD

Welcker's method (1854) is still used as a standard of comparison when studying new methods. It consists in the extraction of all the blood by collecting that which flows from an artery and that obtained by washing out the tissues. The procedure is as follows: A small quantity of arterial blood is collected and diluted to 1 per cent in saline. All the blood flowing from a large artery is then collected, and when the flow ceases the vascular system is washed out by intravenous injection of saline or Ringer's solution. The animal is then cut up into small pieces, which are extracted with saline. The blood and the fluids obtained by washing and extraction are well mixed and diluted until the color is the same as that of the first sample of 1 per cent arterial blood. The total quantity of fluid so obtained divided by 100 corresponds to the total blood volume of the animal.

Bischoff (1855) applied the method in man, using the bodies of two criminals who had been beheaded. The total amount of blood thus determined was found to be equal to 7.7 per cent of the body weight. This method has limited applications, as even in experimental animals it can be used only when survival is not indispensable. The determination is also subject to certain causes of error: (*a*) the pigment in muscle is extracted; (*b*) cloudiness of the fluid makes the colorimetric comparison difficult; (*c*) some erythrocytes can remain in the clots or in the small capillaries.

INDIRECT METHODS

Usually only the total plasma volume or total red cell volume is measured; then the plasma-cell ratio is determined by means of the hematocrit and thus the total blood volume can be approximately established.

There are two types of indirect methods: (*a*) a certain quantity of fluid is injected intravenously and the dilution suffered by a normal constituent of the blood, *e.g.*, erythrocytes or proteins, is measured; (*b*) a certain quantity of a foreign substance is introduced into the circulation, and once it has been distributed throughout the blood, its concentration is measured. Methods of the second type are the only ones now in use.

Carbon monoxide method.[1] This method is based on the fact that CO makes a stable combination with the hemoglobin in the erythrocytes. The oxygen capacity of the subject's blood is determined, *i.e.*, the

[1] First used by Grehant and Quinquaud in animals (1882) and by Haldane and Lorrain-Smith in man (1900). It has been considerably improved by Chang and Harrop (*J. Clin. Investigation*, **5**, 393, 1928). CO is no longer determined colorimetrically, but by the more accurate van Slyke manometric method.

maximum quantity of oxygen absorbed by 100 cc. of blood. The oxygen capacity is the same as the CO capacity. The subject then breathes into a bag which contains a known volume of CO mixed with oxygen. Since CO is toxic, a small quantity should be given so that only a small percentage (about 15 per cent) of the hemoglobin is transformed into carboxyhemoglobin. The concentration of CO in the blood is determined, and the blood volume is calculated. For example, the inhalation of 120 cc. CO has saturated 15 per cent of the hemoglobin in the blood, which has a maximum oxygen capacity (CO capacity) of 20 cc. per cent; therefore $(120 \times 100)/15 = 800$ cc. of gas would be needed to saturate all the hemoglobin in the circulation. As the $O_2(CO)$ capacity is 20 per cent, the total blood volume will be $(800 \times 100)/20 = 4{,}000$ cc. Fixation of CO by hemoglobin in the muscle fibers (myohemoglobin) is a cause of error in this method. The oxygen capacity of the blood is diminished by the inhalation of CO; therefore this method should not be used in cases of anemia, heart insufficiency, or other conditions in which the respiratory function of the blood is impaired.

Radioactive iron method. Radioactive iron is given to a donor belonging to group O (see page 59) so that it will be found in the erythrocytes. A sample of blood is drawn and its radioactivity is measured. A known quantity of this radioactive blood is injected into the blood stream of the subject in which the blood volume is to be determined. The dilution of the radioactivity in the recipient's blood is measured, and the total blood volume can be calculated. This is a very accurate method, and its results are more reliable than those of the dye method.

Dye method. This is the method most frequently used. A measured amount of a colloid dye is injected intravenously, and by determining its dilution, the blood volume can be calculated. The dye must fulfill the following requisites: (*a*) it must be innocuous; (*b*) it must diffuse very slowly out of the blood vessels; (*c*) it must not stain the erythrocytes or other tissue cells; (*d*) it must mix uniformly throughout all the plasma in the body; (*e*) it must be possible to determine its concentration in plasma accurately, even when there is turbidity or hemolysis. Many dyes fulfill these conditions; those most used have been vital red, congo red, trypan red, and trypan blue, but now T 1824 (sometimes called Evans' blue) is preferred. The concentration in plasma is measured by spectrophotometry with a photoelectric colorimeter. The technique of this method has been studied and perfected in its details in several animal species, and it has been applied to man in health and disease.[1] The procedure is as follows: A measured quantity of the dye is injected into a vein of the arm. A 7-min. period is allowed for a thorough mixing of the dye in the plasma, after which a sample of blood is drawn from a vein of the other arm. The concentration of dye in the plasma is measured, and the total plasma volume is calculated (Gregersen, Gibson, and Evans). The plasma-cell ratio is measured with the hematocrit (see Chap. 1), and the total blood volume is calculated.

The distribution of the dye is dependent on the velocity of the circulation. This method therefore measures only the blood which is actively circulating, not that which is stored.

THE NORMAL BLOOD VOLUME

The blood volume can be measured in the basal state or in different physiologic conditions, *e.g.*, exercise. To measure it in the basal state the subject must be fasting, lying down and completely at rest both mentally and physically. The basal blood volume is fairly constant in the same subject, even when measured on different days.

The results obtained with the different methods vary to some extent. The carbon monoxide method gives a basal blood volume of 7.1 to 7.5 per cent of the body weight. The dye method gives higher figures, from 8 to 10 per cent of the body weight. The greater values probably exceed the true blood volume.

The blood volume is proportional to the body weight; it is not a linear function of weight, but varies in relation to $W^{0.72}$ (W = body weight). A child therefore has a greater blood volume per kilogram of body weight than an adult, and a small animal than a large one. After puberty the total blood, plasma, and cell volumes are greater in man than in woman. Gibson and Evans, using the dye method, found an average of 7.7 liters per 100 kg. in man and 6.6 liters per 100 kg. in woman; and in weight 8.2 kg. per 100 kg. and 7 kg. per 100 kg.

The blood volume is more closely proportional to body surface than to body weight.

[1] GREGERSEN, M. J., *J. Lab. & Clin. Med.*, 29, 1266, 1944.

Gibson and Evans give an average of 2,923 cc. per sq. m. in man and 2,523 cc. per sq. m. in woman.[1]

Plasma volume is more constant than cell volume and varies little in the same subject. The average per kilogram is 43 cc. (38 to 58 cc.) in man and 41 cc. in woman; per square meter of body surface it is 1,700 cc. in man and 1,600 cc. in woman.

Distribution of blood in the body. Bazett has calculated that in an adult with a total blood volume of 5.2 liters, this would be distributed as follows: 250 cc. in the heart; 1,300 cc. in the pulmonary circuit; 550 cc. in the arteries, 300 cc. in the capillaries, and 2,250 cc. in the veins (*i.e.*, 3,100 cc. in the major circuit—arteries, capillaries, and veins). The remaining 550 cc. is probably to be found in blood reservoirs (liver, spleen).

VARIATIONS AND REGULATION OF THE BLOOD VOLUME

Changes can take place in the volume of the whole blood or in that of only one of the blood constituents. The following variations can be observed:

1. Total blood volume can be transitorily diminished by hemorrhage or increased by blood transfusion.
2. Erythrocyte volume can diminish, as in anemia, or increase, as in polycythemia.
3. Leukocyte volume is increased in leukocytosis and diminished in leukopenia.
4. Plasma volume can diminish, as is observed in cases of severe burns in which there is transudation of plasma on the burned surfaces. It is increased by transfusion of plasma, and for a short time after intravenous injection of saline solution.
5. Plasma water diminishes in anhydremia (lack of water in the blood) consequent to the deficient ingestion of water, especially in a hot, dry climate (deserts), or to loss of water through diarrhea, polyuria, profuse sweating, etc. In these cases the total plasma volume diminishes because of the loss of salts and water, the concentration of plasma proteins increases, and the hematocrit reveals an increase in the relative erythrocyte volume; this condition is known as hemoconcentration. The increase in plasma protein concentration can be demonstrated by chemical analysis or (more easily and rapidly, and with sufficient accuracy for clinical purposes) by the changes in the refractometric index or the specific gravity.

Rowntree's terminology has been widely adopted to describe the different alterations in the blood volume. *Normovolemia* is the term used for a normal blood volume, *hypovolemia* for a decreased blood volume, and *hypervolemia* for an increased blood volume. Each of these three states can be subdivided into three, according to the proportions of erythrocytes and plasma. When the ratio of cells to plasma is normal, the blood condition will be normocythemic; it will be polycythemic when the proportion of erythrocytes increases and oligocythemic when this proportion decreases. Therefore with regard to blood volume and the plasma-cell ratio, there are nine possible blood states (Fig. 4).

The blood volume is the result of a dynamic equilibrium. Thus, the plasma volume results from the balance of water outgoing from the blood vessels and incoming from the tissue fluids. The main force which sends water out from the capillaries is the blood pressure, and the principal one for retaining or reabsorbing water is the osmotic pressure of the plasma proteins. After blood is lost by hemorrhage, the blood pressure falls and the plasma proteins attract water from the tissues; in this way the blood volume is rapidly restored. Intravenous injection of saline solution increases the capillary pressure and dilutes the plasma proteins. The blood volume is increased for only a very short time, however; within 30 min. it has returned to the initial level, as water and salts pass out into the tissue fluids and are later eliminated by the kidneys. To obtain a lasting increase in the blood volume it is necessary to transfuse whole blood, or plasma, or serum albumin; in this way water from the tissue fluids will be attracted into the blood vessels, the blood volume will be restored, and consequently the blood pressure will be high. Transfusion of blood, plasma, or serum albumin is a therapeutic measure of great value in traumatic and surgical shock and in cases of severe burns, in which the blood volume

[1] The blood is approximately 8 per cent of the body weight, and it can be calculated by multiplying the body weight by 8 and dividing it by 100. Thus a subject weighing 70 kg. has a blood volume of about 5.6 liters. It is useful to remember this in dealing with cases in which bleeding or blood transfusion must be performed.

diminishes, there is a decreasing venous return to the heart, and the blood pressure falls to a low level. It has also made possible severe and prolonged operations which could not otherwise have been tolerated by the patients. In severe hypovolemia appropriate measures should reaches a maximum of 23 per cent for whole blood and 25 per cent for plasma. The increase in plasma is greater than that of whole blood (oligocythemic hypervolemia) between the eighth and ninth months. The blood volume returns to normal in a few weeks after delivery.

Volume normal or normovolemia
Simple normovolemia
Polycythemic normovolemia
Oligocythemic normovolemia.

be taken as soon as possible or disturbances in the circulation will become irreversible, and in spite of treatment, the patient will die (see Chap. 7, Hemorrhage and Transfusion).

Physiologic Variations

Changes in the erythrocyte volume can occur rapidly or slowly. Rapid changes are caused by the retention of erythrocytes in the blood stores, especially in the spleen, or inversely, by the release of stored erythrocytes by contraction of the spleen, as occurs in muscular exercise, emotional states, anoxia (lack of oxygen), etc. Slow variations are due to an increase in the formation or destruction of red cells.

Apart from the increase in basal blood volume due to growth, which has already been mentioned, there is an increase caused by pregnancy. This increase has a gradual onset and

After meals or the ingestion of fluid a very small and transitory increase in blood volume can be observed. Water is rapidly taken up by the tissues and then eliminated by the kidneys, so there are only insignificant changes in blood volume even after copious drinking.

An increase in the temperature of the environment produces an increase in the total erythrocyte volume, due to contraction of the spleen, and an increase in total plasma volume, due to reabsorption of water from the tissue fluids. Cold, on the contrary, diminishes the plasma volume, because water passes out into the tissues, especially the skin, muscles, and liver, without there being any change in the total body water. The central nervous system plays a part in regulating this water displacement, but local mechanisms can also be demonstrated by cooling a limited part of the body.

On changing from the prone to the erect position, plasma volume can diminish by as much as 15 per cent in 30 min. This is due to the passage of fluid out into the tissues of the lower limbs. Exercise produces first an increase in the total blood volume and in the red cell volume, due to contraction of the spleen. Afterward water diffuses from the blood plasma into the tissues because of vasodilatation and the increase in the osmotic pressure of the tissue fluids; this latter is produced by the breaking up of large molecules into smaller ones in the course of muscular contraction. Finally sweating provoked by exercise causes loss of water and salts, so the plasma volume diminishes even more and hemoconcentration is more marked.

Altitude, such as is experienced in aviation or climbing a high mountain, produces an increase in the erythrocyte volume due to contraction of the spleen. After a time at high altitude the production of erythrocytes is stimulated and contributes to maintain the polycythemic condition. These changes are caused by the low partial pressure of oxygen.

Pathologic Variations

There are many abnormal conditions in which the blood volume diminishes. Hemorrhage causes a loss of whole blood. There is at first a normocythemic hypovolemia, but water is very rapidly reabsorbed from the tissues, the blood is diluted, and the plasma volume increases. This dilution can be demonstrated by the hematocrit, which shows a relative decrease of the erythrocytes, and by the decrease in the concentration of plasma proteins. Dilution is greater and lasts longer in proportion to the amount of blood lost. Hemorrhage provokes contraction of the spleen, which discharges stored erythrocytes into the circulation; later erythropoiesis (formation of erythrocytes) is stimulated and the normal erythrocyte concentration is restored.

There are three principal mechanisms that cause a decrease in the fluid part of the blood: (*a*) the passage of water and salts into the tissues; (*b*) the loss of water and salts from the body; and (*c*) the loss of plasma.

In traumatic and surgical shock, acute adrenal insufficiency, and diabetic coma, water and salts diffuse from the blood vessels into the tissues; there is a progressive decrease in plasma volume and hemoconcentration (increase in the concentration of erythrocytes and plasma proteins) that can be fatal. Anhydremia and hemoconcentration (polycythemic hypovolemia) are also caused by intense dehydration due to insufficient intake or excessive loss of water, such as occurs in diarrhea, polyuria, profuse sweating, repeated vomiting, high intestinal obstruction, etc. Hemoconcentration is in some cases so marked that it is difficult to extract blood from the depleted veins. The thick, viscous aspect of the blood in the extreme dehydration of cholera is described in all the classic treatises. Polycythemic hypovolemia is present in cases of severe burning, mainly as a result of the loss of plasma (plasmorrhea) into the damaged tissues. Plasmorrhea and hemoconcentration are also observed in pulmonary edema and in dysentery.

In myxedema caused by thyroid insufficiency, both the plasma and erythrocytes are diminished, but there is a certain degree of oligocythemia. In anemia the whole blood volume is only slightly diminished; the decrease in erythrocyte volume is compensated in part by a moderate increase in plasma volume (oligocythemic hypovolemia). The blood volume may be normal in chronic nephritis, but the erythrocyte volume is decreased (oligocythemia). In obesity the blood volume per kilogram is reduced, but when calculated with regard to the body surface it is normal.

Polycythemia vera consists in an increase in whole-blood volume; the erythrocyte volume increases more than the plasma volume, so there is a polycythemic hypervolemia. Chronic anoxia (lack of oxygen) of pulmonary or cardiac origin also causes polycythemia. In acute congestive cardiac insufficiency there is a 20 to 50 per cent increase in plasma volume. Cirrhosis of the liver is also accompanied by an increase in plasma volume. In leukemia the leukocyte and plasma volumes are increased.

Variations in blood volume caused by disease are of vital importance in some cases. Hypovolemia and hemoconcentration, if sufficiently marked and prolonged, cause a decrease in the blood flow through the tissues and consequently an insufficient supply of oxygen (anoxia); anoxia increases the permeability of the capillaries, which accentuates the loss of water and plasma proteins from the blood. Thus a vicious circle is established: plasmorrhea → hypovolemia → hypotension → anoxia → plasmorrhea. If adequate treatment by transfusion of blood, plasma, or serum albumin is not given before the disturbance has progressed too far, death will occur.

An increase in the circulating blood volume increases the work of the heart. An increase in the erythrocyte concentration (polycythemia) increases blood viscosity; hence the peripheral resistance and

the work of the heart are increased, and the circulation tends to become sluggish.

CHAPTER 3

The Erythrocytes[1]

Functions. The red blood cells or erythrocytes, which give the blood its typical scarlet color, have the following functions:

1. They carry oxygen and carbon dioxide.
2. They take part in the regulation of the acid-base equilibrium.
3. Their coloring matter, hemoglobin, gives rise to the bile pigments and allied substances.

Shape and size. Under the microscope the erythrocytes are seen to be biconcave disks, reddish yellow in color, flexible, and elastic; their shape can be passively changed by outside forces, but afterward they recover their original aspect. The erythrocytes of fishes, amphibians, reptiles, and birds have a nucleus and usually are biconvex with an elliptic contour. The erythrocytes of mammals have no nucleus and are discoid in form, except in some Camelidae (llama, guanaco) in which they have an elliptic shape. In man the erythrocytes are discoid except for a few exceptional cells which have an oval or elliptic shape (ovalocytosis). In certain subjects (Africans and Mediterraneans) sickle-shaped erythrocytes are found (drepanocytosis).

The mammalian erythrocyte is well adapted to its respiratory function. The lack of a nucleus, the small size, and the discoid biconcave shape allow the transport of a relatively large amount of hemoglobin, distributed near the surface of the cell so as to facilitate gaseous exchange. These nonnucleated erythrocytes are highly differentiated cells that have lost their reproductive power and consume much less oxygen than the nucleated erythrocytes. The biconcave form is a great advantage (Ponder), as for a given mass it assures a maximum surface and the proximity to this surface of even the most deeply placed molecules.

The surface of each erythrocyte is 128 sq. μ (120 to 140 sq. μ). The total surface of all the erythrocytes in the organism has been estimated at 3,500 sq. m., nearly 2,000 times the body surface. Bürker has calculated that the amount of hemoglobin per square micron (sq. μ) of erythrocyte surface is almost constant (about 32×10^{-14}) in all mammals, in spite of differences in size and concentration of erythrocytes and in hemoglobin concentration.

The size of the erythrocytes can be determined by measuring the diameter, the thickness, or the volume of the cell. The average diameter in dry preparations varies with the technique used for preparing the specimens; it is 7.2 μ (6 to 8 μ) according to Price-Jones, or 7.5 μ according to Wintrobe; in plasma it is slightly larger, approximately 8.5 μ. CO_2 and acidosis increase the diameter, because water and Cl enter into and swell the erythrocyte. Therefore, in venous blood the erythrocytes are larger (0.5 μ) than in arterial blood. Size-frequency curves (Fig. 5), obtained by measuring large numbers of erythrocytes, show that the great majority have a size near the mean (normocytes), but there are a few small cells (microcytes) and a few large cells (macrocytes).[1] In cases of pernicious anemia the average diameter is larger than the normal and the dispersion in size is greater (Figs. 5 and 6), because of the presence of large erythrocytes developing from primitive cells called megaloblasts. In some types of

[1] The erythrocytes were accurately described for the first time by Leeuwenhoek (1673). Hemoglobin was obtained in crystallized form by Funke (1851), and its respiratory function was demonstrated by Hoppe Seyler (1867). Vierordt made the first red cell counts in 1852. Neumann (1868) observed the formation of erythrocytes in the bone marrow.

[1] Price-Jones, C., *J. Path. & Bact.*, **40**, 503, 1935.

anemia there is a great disparity in the size of the erythrocytes (anisocytosis), and sometimes they have abnormal and varied shapes (poikilocytosis).

The normal thickness of the red cells varies from 1.8 to 2.2 μ, but in pathologic cases
Fig. 5. Distribution curve of erythrocyte diameter in several blood conditions. (*Whitby, L. E. H., and C. J. C. Britton, "Disorders of the Blood," J. & A. Churchill, London, 1939.*)

(hemolytic anemia, congenital hemolytic jaundice) it can increase considerably and the erythrocytes take on a spheroid shape (spherocytes). This shape is observed *in vitro* when the erythrocytes are placed in a hypotonic solution. In these cases the erythrocytes increase in thickness but not in diameter, as can be seen by dividing the diameter by the thickness; the average quotient in normal subjects is 3.4 (2.5 to 4) (Fig. 6). The easiest way of measuring the true size of the erythrocytes is to determine the mean corpuscular volume (see below).

Concentration. (Fig. 7.) Well-nourished adult men have about 5,400,000 erythrocytes per cu. mm. (4,500,000 to 6,000,000); the corresponding figure for women is 4,800,000 (4,000,000 to 5,500,000) per cu. mm. The newborn have a high concentration of large erythrocytes; in the course of the first few weeks of life the concentration diminishes and normal-sized erythrocytes appear. During childhood the concentration of erythrocytes remains low, and rises during puberty to the adult level. During pregnancy there is a slight decrease in the concentration due to an increase in plasma volume; the drop is usually not greater than 15 per cent of the normal figure.

Variations in the erythrocyte concentration are produced by one of the following mechanisms:

1. Excessive or insufficient production.
2. Excessive destruction.
3. Loss of erythrocytes (hemorrhage).
4. Increase or decrease in plasma volume.
5. Rapid mobilization of erythrocytes stored in the spleen.

An increase in erythrocyte concentration is called "polycythemia," and a decrease "oligocythemia." Three types of polycythemia can occur:

1. Relative polycythemia, when the increase in concentration is due to loss of plasma or water (hemoconcentration).
2. Transitory polycythemia, when erythrocytes are rapidly discharged from the blood reservoirs.
3. Absolute polycythemia, when the total amount of erythrocytes in the blood is increased.

The influence of oxygen and nutritional factors which regulate erythrocyte concentration will be discussed in Chap. 5.
Fig. 6. Volume, diameter, and thickness in relation to fragility of erythrocytes. *M.C.V.*, mean corpuscular volume; *M.C.D.*, mean corpuscular diameter; *M.C.A.T.*, mean corpuscular average thickness. Chemical composition. (See Tables 1 and 2, pages 8 and 9.) Water makes up about two-thirds of the mass of the erythrocyte. Hemoglobin constitutes 90 to 95 per cent of the solid content, about

Modified from Wintrobe.

34 gm. in 100 cc. of the circulating erythrocytes. Other proteins make up from 0.5 to 1 per cent of the cell mass. Nucleoproteins have been found in the stroma. Phospholipids are in higher concentration than in plasma; there are also cholesterol esters and free cholesterol, cerebrosides, and small quantities of neutral fats. Reducing substances which are not glucose or any other sugar are found in the erythrocytes. In the erythrocytes of man and several animals, K is the predominant cation; in other species (cat, dog) Na predominates. The erythrocyte has a higher nonprotein N concentration than plasma. The erythrocytes have catalase, which can be demonstrated by adding red cells to hydrogen peroxide, whereupon bubbles of molecular

oxygen are set free. Hemoglobin acts as a peroxidase and transports oxygen from hydrogen peroxide to a substrate. This reaction is used to reveal the hidden presence of blood in feces and in body fluids and secretions in pathologic cases. Substrates which take on a typical color on oxidation are employed (Mayer's reagent, tincture of guaiac, benzidine).

Table 4. Erythrocyte Volume in Different Types of Anemia

Type of anemia	*Mean corpuscular volume, cu. μ*	*Mean corpuscular hemoglobin, γγ*	*Mean corpuscular concentration, %*	*Mean diameter of erythrocytes, μ*
Macrocytic	95–160	30–52	31–38	7.8–8.5
Normocytic	80–94	27–32	33–38	6.8–8.0
Microcytic	70–79	22–26	31–38	6.5–8.5
Microcytic hypochromic	50–71	14–21	21–29	5.8–6.5

Absolute corpuscular values. Three measurements are necessary to determine the condition of the erythrocytes in health and in disease. These measurements are (*a*) the erythrocyte volume (with the hematocrit); (*b*) the red cell count; (*c*) the hemoglobin concentration. From the data obtained by these determinations, the following values can then be calculated:

1. Mean corpuscular volume (MCV), *i.e.*, the average volume of each erythrocyte expressed in cubic microns (cu. μ):

$$\frac{\text{Volume of erythrocytes (in cc.) in 1,000 cc. of blood (hematocrit)}}{\text{Erythrocytes per cu. mm. (in millions)}} = 87 \text{ (80 to 94) cu. } \mu$$

2. Mean corpuscular hemoglobin (MCHb), *i.e.*, average amount of hemoglobin in each erythrocyte in micro-micrograms ($\gamma\gamma$):

$$\frac{\text{Hemoglobin (in gm.) in 1,000 cc. of blood}}{\text{Erythrocytes per cu. mm. (in millions)}} = 29 \text{ (27 to 32) } \gamma\gamma$$

3. Mean corpuscular hemoglobin concentration per cent (MCHbC), *i.e.*, the amount of hemoglobin in 100 cc. of erythrocytes:

$$\frac{\text{Hemoglobin (in gm.) in 100 cc. of blood}}{\text{Volume of erythrocytes in 100 cc. of blood (hematocrit)}} \times 100 = 34 \text{ (33 to 38) gm.}$$

Anemias are classified according to the size of the erythrocytes into macrocytic, normocytic, and microcytic. When the corpuscular hemoglobin is also diminished, the anemia is called hypochromic.

The mean corpuscular thickness is calculated from the mean corpuscular volume (*MCV*) and the mean corpuscular diameter (*MCD*) in the following way:

$$\frac{MCV}{\pi(MCD/2)^2} = 2.1 \text{ (1.7 to 2.5) } \mu$$

Hematic indexes: These are values given by comparing the result obtained in a particular case with the normal value. These indexes should be abandoned in favor of the absolute values.

The color index is calculated in the following way:

$$\frac{\text{Hemoglobin, \% of normal (gm. in 100 cc.} \times 6.9)}{\text{Erythrocytes, \% of normal (millions per cu. mm.} \times 20)} = 1 \text{(0.9 to 1.1)}$$

The normal erythrocyte count is considered as 5,000,000 and the normal hemoglobin 14.5 gm. per cent (Wintrobe).[1]

The color index is high in pernicious anemia, which has for this reason been wrongly called "hyperchromic" anemia. The erythrocyte contains more hemoglobin because it is larger, but the hemoglobin concentration is normal (34 gm. per 100 cc. of cells). Macrocytic and microcytic anemias are hypochromic when the corpuscular hemoglobin and the hemoglobin concentration are diminished.

The saturation index is calculated thus:

$$\frac{\text{Hemoglobin, \% of normal (gm. in 100 cc.} \times 6.9)}{\text{Volume of packed cells (of 100 cc.)} \times 2.3} = 1 \text{(0.8 to 1.2)}$$

The volume index is calculated thus:

$$\frac{\text{Volume of packed cells (of 100 cc.)} \times 2.3}{\text{Erythrocytes per cu. mm. (in millions)} \times 20} = 1 \text{(0.9 to 1.1)}$$

[1] The average normal figure in Buenos Aires is 5,400,000 and 15.6 gm. per cent.

Agglutination. The erythrocytes of shed blood form groups, similar to piles of coins, known as "*rouleaux.*" *Rouleaux* formation is seen within the vessels only when the blood circulates very slowly. If the shed blood is shaken up, the erythrocytes separate from each other. In some cases, as in pregnancy, acute infections, malaria, etc., the formation of *rouleaux* is marked and the piled erythrocytes are separated from the plasma, but on shaking, the *rouleaux* break up. These are phenomena of pseudoagglutination.
Fig. 8. Westergren's technique for determining sedimentation rate. Normal in the two tubes on the left and accelerated in the two on the right.

When blood from one subject is mixed with serum from another subject, the erythrocytes of the first subject may remain dispersed as in their own plasma, or they may aggregate in clumps which are not broken up by shaking; this phenomenon is called agglutination. The serum in this case has an agglutinating factor, or agglutinin, for the erythrocytes, known as hemagglutinin; more specifically it is called "isohemagglutinin," because it acts on the erythrocytes of subjects belonging to the same animal species. The presence or absence of agglutinin in serum and of the corresponding factor (agglutinogen) in the erythrocytes has led to the classification of human beings in four principal blood groups (see "Blood groups," Chap. 7). The serum of an animal species can also have agglutinins for the erythrocytes of other species; those are called heteroagglutinins. The repeated injection of erythrocytes of one species into an animal of another species provokes the formation of heteroagglutinins in the blood of the latter; as this is a process of immunity, the agglutinins so formed are known as immune hemagglutinins.

The erythrocytes are agglutinated by hemolytic serum obtained by immunization (see "Hemolysis"); by some snake venoms, *e.g.*, those of *Bothrops;* by several animal and plant toxins; and by some chemical agents.

Suspension stability. Erythrosedimentation. When blood in which clotting is prevented is left standing in a long tube placed vertically, the erythrocytes sink to the bottom, because their specific gravity is greater than that of plasma. Above the red cells a thin layer of leukocytes is deposited, covered by plasma in which the platelets are suspended. Blood is a suspension of cells in plasma, the stability of which can be measured by the velocity of sedimentation of the erythrocytes. There are several methods for determining the suspension stability of the blood; Westergren's technique is the most simple and commonly used.

Blood is collected, mixed with one-fifth its volume of a 3.8 per cent sodium citrate solution, and placed in a graduated pipet 300 mm. long. The pipet is left standing, and at the end of 1 hr. the length of the column of separated plasma is read (Fig. 8). Wintrobe's hematocrit can be used for this purpose, leaving the tube and anticoagulant standing for 1 hr. before centrifugation. Heparin (1 mg. per cc. of blood) is also used instead of citrate as an anticoagulant.

The sedimentation of corpuscles suspended in a fluid depends on the specific gravity and mass of the corpuscle and on the resistance that the fluid exerts on the surface of the corpuscle. The interaction of the factors that play a part is expressed in Stokes's law:

$$V_s = \frac{2r^2(S - S_1)g}{9\eta}$$

where V_s is the sedimentation velocity, r is the radius of the corpuscle, S is the specific gravity of the corpuscle, S_1 is the specific gravity of the fluid, g is the gravitation constant, and η is the viscosity coefficient of the fluid.

For sedimentation to take place $S - S_1$ must have a positive value, as occurs in blood, where the corpuscles are heavier than the plasma.

The sedimentation rate is greater when the corpuscles are larger; the aggregation of erythrocytes into *rouleaux* accelerates their sedimentation. Variations in the sedimentation rate depend almost exclusively on plasmatic factors, and little or not at all on the erythrocytes. Red cells from normal blood sink rapidly when placed in plasma from blood with a high sedimentation rate, and red cells from blood with a high sedimentation rate sink at a normal rate in normal plasma. The most important factor is the concentration of fibrinogen, to which the sedimentation rate is directly proportional; globulin concentration is not so important, and serum albumin even less. When fibrinogen concentration increases, the erythrocytes conglomerate into larger *rouleaux* and thus sink more rapidly. Apparently the negative charge, which keeps the erythrocytes dispersed, is diminished in this case; also there seems to be an increase in the surface tension and hydrophilia of the erythrocytes. When fibrinogen concentration diminishes, as in defibrinated blood and in some cases of shock, the erythrocyte sedimentation rate is very low. Sedimentation rate increases when the erythrocyte concentration diminishes, *e.g.*, in anemia.

The blood plasma of children has a low globulin concentration and a low sedimentation rate; the newborn child has a rate of 0.2 to 0.5 mm. per hr. With age the rate increases to an average of 3.3 (2 to 7) mm. per hr. in adult men. The plasma of adult women has a higher globulin concentration and therefore a faster sedimentation rate; the average is 7.5 (3 to 10) mm. per hr. The sedimentation rate increases during pregnancy up to 45 mm. toward the end, and diminishes gradually after delivery to 41 mm. in 1 month and 20 mm. in 2 months (Fåhraeus, 1918). Oxygen accelerates erythrosedimentation because it increases the size of the erythrocytes; CO_2 retards sedimentation.

In cyanosis (lack of oxygen in the blood) the suspension stability of the blood is greater than normal. In polycythemic conditions erythrosedimentation is slow. In acute general infections (pneumonia, rheumatic fever, etc.), local infections (abscesses, arthritis, pelviperitonitis, etc.), the acute periods of chronic infections (tuberculosis, leprosy, etc.), and malignant tumors, there is an increased sedimentation rate. The changes in sedimentation rate are not specific for any particular disease, but nevertheless they are very useful in medical practice; because an increase reveals the existence of inflammation or tissue destruction, it can therefore be used to follow the course of such a process, and to establish its diagnosis and prognosis.

HEMOLYSIS

Description. Normally the hemoglobin of the erythrocytes does not diffuse out into the plasma or into isotonic saline solutions. Several physical and chemical agents can act on the erythrocytes so as to set free the hemoglobin, which then diffuses into the fluid surrounding the red cells; the latter seem to disappear and the fluid becomes darker and transparent. This dissolution of the erythrocytes is called "hemolysis," and the blood is said to be "hemolyzed" or "laked." By centrifugation of laked blood, especially if certain salts are added, a small amount of cell residue is obtained.[1] This is the stroma of the erythrocytes, consisting in the protein and lipid framework which holds the hemoglobin and electrolytes.[2]

Permeability of the erythrocyte. The erythrocyte membrane is easily permeable to the anions Cl^-, CO_3H^-, and to the cation H^+; also to glucose, amino acids, urea, and NH_4. It is not permeable to proteins and does not let the plasma proteins enter the erythrocyte, nor the hemoglobin diffuse into the plasma. It was thought to be impermeable to Na^+, K^+, Ca^{++} and Mg^{++}, but by using radioactive K and by other methods it has been possible to demonstrate that small amounts of these ions pass through the membrane.

[1] The erythrocytes are separated by centrifugation and washed twice in saline solution. To the mass of cells obtained by centrifugation, two volumes of distilled water saturated with ether are added. Then, drop by drop, a 1 per cent solution of potassium acid sulfate is added until the solution has the same opacity as blood. By centrifugation the stroma of the erythrocytes is separated and can be washed with distilled water.

[2] Hemoglobin is retained by the erythrocyte even after it has been damaged mechanically or divided into fragments, if the cells are in an isotonic solution.

The fragility (resistance) of erythrocytes. The properties of the erythrocyte are sometimes explained by considering it as a minute osmometer surrounded by a semipermeable membrane, made up of a mosaic or of concentric layers of proteins, lipids, and cholesterol. The membrane of the erythrocyte is not truly semipermeable, as it lets through not only water but also some substances in solution; it has a selective permeability. The contents of the erythrocyte have an osmotic pressure equivalent to that of blood plasma. When the plasma is diluted, water penetrates into the erythrocytes, which swell and take on a spheroid shape; finally hemoglobin diffuses out as if the membrane had been broken or had become permeable.

The erythrocytes retain their size and shape when suspended in an isotonic solution. Such a solution can be prepared by dissolving NaCl in water—0.95 per cent for men, and 0.93 per cent for women.[1] If erythrocytes are suspended in NaCl solutions decreasing by 0.02 per cent from 0.6 per cent concentration, hemoglobin will begin to diffuse out of the cells and color the fluid at a concentration of 0.48 to 0.40 per cent; the more fragile erythrocytes cannot resist this degree of hypotonicity (minimum resistance). Total hemolysis will be observed at concentrations of 0.34 to 0.30 per cent, when even the most resistant cells let their hemoglobin escape (maximum resistance). The spheroid erythrocytes are fragile, while flat, elongated erythrocytes are resistant. The resistance of the cells is modified by the temperature, pH, and ionic equilibrium of the solution. Special techniques have been devised to measure the fragility or resistance of the erythrocytes taking all these factors into account.[2] A more accurate study requires the determination of the amount of hemoglobin diffusing out at each concentration level.

The fragility of the erythrocytes is considerably increased in congenital hemolytic jaundice (Fig. 6) and in some types of purpura; frequently the fragile cells have a spheroid shape. The resistance of the erythrocytes is increased in pernicious anemia, and markedly increased in infantile erythroblastic anemia; it is also increased in jaundice due to obstruction of the bile ducts. Red cells are not hemolyzed in an isotonic solution of sucrose. On the other hand, a solution of urea hemolyzes the erythrocytes because urea diffuses into the cells so that its concentration is the same within and without the erythrocyte; therefore the erythrocytes swell out and hemolysis occurs.

Physical and chemical hemolytic agents. Hemolysis can be produced by intense and prolonged shaking; electrical discharges; repeated freezing and thawing; heat (65°C.); organic solvents, such as ether, alcohol, toluene, chloroform, benzene, etc.; alkalis, especially NH_3; bile salts; saponin, which is very active but can be neutralized by cholesterol; toluylene-diamine; phenylhydrazine; and several arsenic compounds. Some of these substances, *e.g.*, phenylhydrazine, have been used in the treatment of polycythemia to diminish the excessive concentration of erythrocytes.

Many plant and animal substances and toxins have hemolytic activity. Among these are some of the snake venoms, which contain phosphatidases; they attack lecithin and cephalin, and on separating the oleic acid from the molecule, powerful hemolytic substances are formed, lysolecithin and lysocephalin (Delezenne and Fourneau, Levene). Cobra (*Naja tribudians*) venom acts directly on the phosphatides of the erythrocytes. Other snake venoms act on the lecithin in the plasma, which must be added when experimenting with cells suspended in saline solution. Some of the bacteria, *e.g.*, streptococci, *Bacillus perfringens*, have hemolytic activity.

Hemolytic serum. (See Chap. 9.) Blood serum hemolyzes the erythrocytes of other species, and can acquire or increase this activity by immunization. For example, repeated injections of sheep erythrocytes into a rabbit produce strong hemolytic activity in the serum of the rabbit against sheep erythrocytes. The erythrocytes act as an antigen and provoke the active formation of an antibody (hemolysin). This hemolysin is made up of two parts, the amboceptor (Ehrlich), or sensibilisatrix (Bordet), which is specific for the erythrocytes used as antigen, and the complement (Ehrlich), or alexin (Bordet), which is not specific. By heating the hemolytic serum at 56°C. for 30 min., the complement is destroyed, while the amboceptor resists this temperature. Hemolytic activity can be restored by adding fresh serum of any species, *e.g.*, guinea pig, and thus replacing the destroyed complement.

[1] Care must be taken to avoid loss of CO_2; otherwise the isotonic concentration of NaCl is 0.9 per cent.

[2] Hamburger recommends the use of Na_2SO_4 instead of NaCl.

Plasma, or serum, usually does not hemolyze the erythrocytes of the same species, but in some cases there are isohemolysins, which can be responsible for accidents in blood transfusion.

In paroxysmal hemoglobinuria, hemolytic crises occur when the patient is exposed to cold, or exercises, or suffers an intense emotional stress. If blood is drawn and kept warm, hemolysis does not occur, but if it is cooled to 5°C. and then warmed to 38°C., there is hemolysis (Donath). Isohemolysins have been found in the blood of patients with hemolytic jaundice.

CHAPTER 4

Hemoglobin and Derived Pigments

HEMOGLOBIN

Functions. Hemoglobin, the respiratory pigment of the blood, has the following functions: (*a*) it takes up oxygen in the lung and transports it in the circulating blood, giving it up to the tissues; (*b*) it helps to carry CO_2 from the tissues to the lung; (*c*) it takes part in the maintenance of the acid-base equilibrium; (*d*) it is the source of bilirubin, which gives rise to urobilin. The color of the blood is due to hemoglobin and to its combinations and derived pigments.

Localization. Hemoglobin is found in several animal tissues. In the blood of vertebrates it is found exclusively in the erythrocytes, of which it is a constant and typical constituent. This localization within the red blood cells has many advantages (Barcroft); thus blood can transport sixty times the oxygen it could carry if it were made up only of plasma. Nevertheless, it has been possible to replace, for a short time, up to 60 per cent of the blood of dogs by a 6 per cent solution of hemoglobin.[1] Hemoglobin that escapes from the cells into the plasma either is picked up by the cells of the reticuloendothelial system, where it is metabolized, or else is eliminated by the kidney.

Structural relations with other pigments. The most widely distributed pyrrolic respiratory pigments are the "hemes," one of which is hemoglobin. Its fundamental chemical nucleus is a pyrrole group; four of these groups unite to form porphyrins. Porphyrins combine with metals Fe, Cu, Co, etc., and form metalloporphyrins. Hemes are ferroporphyrins, *i.e.*, compounds of porphyrin and iron. One of the porphyrins, protoporphyrin 9, type III, by combining with iron forms heme, which joined to a globin gives hemoglobin. A magnesium porphyrin of the isomeric type III is the fundamental group of chlorophyll, the green pigment of plants.

[1] Amberson, W. R., *et al.*, *Am. J. Physiol.*, **116**, 1, 1936; **117**, 230, 1936.

Hemoglobin is a compound of heme and protein (globin). In red-muscle fibers and in cardiac muscle there is myohemoglobin similar to, but not the same as, hemoglobin. In many, probably in all, animal and plant cells there are compounds of heme, called cytochromes (Keilin). These exist in reduced and oxidized forms, as they can take up and lose electrons, thus taking part in oxidation-reduction reactions. Reduced cytochrome takes up oxygen and releases it to the cells. The amount of cytochrome in a tissue is proportional to the respiratory activity of the cells.

By means of spectroscopic studies it has been possible to identify four different cytochromes, known as α, α_3, β, and c.[1]

The cytochromes form part of the oxidation-reduction mechanisms of the tissues. They do not take up oxygen directly but by means of cytochrome-oxidase (indophenoloxidase). Cyanides and other toxic substances (SH, CO, anesthetics) inhibit cytochromeoxidase and suppress its action in tissue oxidation. Cytochrome is oxidated not directly but through the activity of tissue dehydrogenases, which activate hydrogen so that it combines with cytochrome, the latter acting as a hydrogen acceptor. In this way cytochrome behaves as an intermediary in the transfer

[1] Keilin, D., and W. Hartree, *Proc. Roy. Soc., London*, *s.B.*, **127**, 167, 1939.

of oxygen from hemoglobin and plasma to the oxidizable substrate of the cells.

Heme has also been found in certain enzymes, such as peroxidase and catalase.

Physical properties. Hemoglobin (especially in its oxygenated form, oxyhemoglobin) crystallizes, more or less easily according to the animal species from which it comes, into rhombic prisms or needles of the rhombic system. In some species the crystals are typical tetrahedrons (guinea pigs) or plates (squirrels) (Fig. 9). Hemoglobin in water forms colloidal dispersions which do not dialyze nor ultrafilter. It is a dextrorotatory ampholyte, with the iso-electric point at pH 6.78. The size of its molecule can be measured in several ways: (*a*) by testing whether or not it passes through a membrane, the pores of which have been measured by the velocity of diffusion of water through them; (*b*) by ultracentrifugation at high speed (Svedberg); (*c*) by the osmotic pressure of its solutions (Adair).

The spectroscopic method is of fundamental importance in the study of hemoglobin, its combinations, and the pigments derived from it. Oxyhemoglobin shows two bands in the absorption spectrum, situated between the D and E Frauenhofer lines (Fig. 10). The α band is the narrower, darker, and more clearly marked of the two and is placed at 5760 A; the β band is wider and has its middle point at 5413 A. The spectrum of carboxyhemoglobin (COHb) has two similar bands slightly displaced toward the violet end, the α at 5680 A and the β at 5390 A.
Fig. 9. Left: oxyhemoglobin crystals. *a* and *b*, man; *c*, cat; *d*, guinea pig; *e*, hamster; *f*, squirrel. Right: crystals of hemin or hematin chlorhydrate (Teichmann's crystals).

Oxyhemoglobin loses oxygen by the action of reducing agents, such as sodium hyposulfite ($Na_2S_2O_4$), and becomes reduced hemoglobin; both the bands in the absorption spectrum disappear and are replaced by a single one which is wider, has less distinct margins, and has its center placed at 5560 A. Hemoglobin, its compounds, and the pigments derived from it absorb violet and ultraviolet light (Soret's band).

Chemical properties. Hemoglobin is a conjugated protein, made up of 4 per cent heme and 96 per cent globin, which is a histone. Hemoglobin contains C, N, H, O, S, and Fe; the proportion of Fe is fairly constant, about 0.34 per cent. Hemoglobins from different species have the same fundamental structure and properties, but they differ in some of their properties (solubility, readiness to crystallize and shape

of the crystals, velocity of combination with O_2 or CO, amino-acid and S content, etc.). Heme is the same in all hemoglobins, but the globin differs from one species to another. The globin of fetal hemoglobin is not the same as that of adult hemoglobin.

If it is considered that there is at least one atom of Fe in each molecule, the minimum weight possible would be 16,400. The molecular weight of hemoglobin has been determined and found to be about four times this figure—63,000 by ultracentrifugation (Svedberg), and 66,400 by osmotic pressure (Adam). The hemoglobin molecule, therefore, contains four atoms of Fe and is made up of four protein units of 16,400 molecular weight each. This high molecular weight, and the consequently great size of the molecule, are the cause of the colloidal nature of its dispersions. Myohemoglobin has a molecular weight of 16,800 to 17,000; therefore there is only one atom of Fe in each molecule.

Hemoglobin rapidly forms well-defined reversible combinations with oxygen and with carbon monoxide, the substance that is the cause of coal-gas poisoning. These combinations are dependent on the partial pressure of the gas, the temperature, the pH, and the electrolytes in the solution. This property is of primary importance in the respiratory function of hemoglobin, *i.e.*, the capacity to take up, transport, and deliver oxygen; it will be studied in the section on respiration. Each atom of Fe in hemoglobin can combine with one molecule (2 atoms) of oxygen or one molecule of carbon monoxide. (See Chap. 28, The Transportation of Oxygen by the Blood.)

Hemoglobin also combines with CO_2. Globin, not heme, takes part in this combination, which results in a carbamino compound.

$$HbNH_2 + CO_2 \rightleftarrows HbNHCOOH$$
This is one of the ways in which hemoglobin takes part in the transport of CO_2 (see Chap. 30).

Hemoglobin can also combine with nitric oxide (NO), hydrogen sulfide (H_2S), and hydrogen arsenide (H_3As).

Hemoglobin acts as a peroxidase and sets free molecular oxygen from oxygen peroxide. This oxygen can react on tincture of guaiac or on benzidine and gives a colored compound. The reaction is not specific for hemoglobin, but is useful to detect the presence of hemoglobin, and therefore of blood, in feces and other bodily excretions or secretions.

Studies begun by Pauling in 1949 have demonstrated the existence of several types of hemoglobin in man, *e.g.*, HbA (A_1, A_2) found in normal adults; HbF or fetal Hb; HbS found in the sickle-shaped erythrocytes in cases of Cooley's sickle-cell anemia; HbC and HbD.
FIG. 10. Absorption spectra of hemoglobin and some of its derivatives. 1, oxyhemoglobin; 2, carboxyhemoglobin; 3, reduced hemoglobin; 4, methemoglobin.

Oxygen capacity. The reversible combination of hemoglobin with oxygen is known as oxygenation. It is not a true oxidation and its Fe remains in the ferrous (Fe^{++}) state, not passing to the ferric (Fe^{+++}) state. It is usually admitted that 1 gm. of hemoglobin can take up 1.34 cc. of oxygen.[1] This is only an approximate figure, because of the difficulty in obtaining pure hemoglobin; moreover, on drying, hemoglobin loses part of its oxygen capacity. The best samples of crystallized hemoglobin so far obtained have about 95 per cent the oxygen capacity of hemoglobin in fresh blood. The oxygen capacity of 100 cc. of blood is on an average 21 cc. in man (15.4 gm. Hb × 1.34 cc. O_2) and 18.5 cc. in woman (13.8 gm. Hb × 1.34 cc. O_2). This maximum amount is taken up in the presence of oxygen or of air. The capacity to take up CO or NO is the same as for O_2, *i.e.*, 1 gm. hemoglobin can take up 1.34 cc. of any of these gases.

[1] This figure was given by Huffner (1894). Recently Bernhard and Skeggs (*J. Biol. Chem.*, 147, 19, 1934) have found that 1 gm. of hemoglobin can take up 1.36 cc. of oxygen.

Hemoglobin concentration. There are four methods for determining the hemoglobin concentration: (*a*) spectrophotometry; (*b*) measurement of the respiratory capacity; (*c*) estimation of the iron content; and (*d*) colorimetry. The three first mentioned are considered as standard methods; nevertheless there is a small proportion of hemoglobin that does not combine with oxygen, and in some pathologic cases there are slight variations in the iron content of the blood. Normally there are very small amounts of methemoglobin, carboxyhemoglobin, and inactive hemoglobin.[1]

Colorimetric methods are more frequently used in medical practice, because they are simple and sufficiently accurate. Hemoglobinometers are not always well standardized, and it is necessary to control them before using them. The practice of giving the results as a percentage of an arbitrary normal standard should be abandoned in favor of giving the amount of hemoglobin, in grams, in 100 cc. of blood. There are various reasons for this:

1. The figure considered as normal and given the value of 100 varies in different countries, and even in different parts of the same country.
2. The figure 100 corresponds to different amounts of hemoglobin in the different hemoglobinometers; thus the Haldane standard is 13.4 gm. per cent, Sahli's is 17.3 gm. per cent; the German Society of Internal Medicine gives 16 gm. per cent.

Hemoglobin concentration in 90 per cent of healthy men varies between 14 gm. and 18 gm. per 100 cc. of blood, and between 12 gm. and 15.5 gm. per 100 cc. in women.[2] During the last months of pregnancy there is a decrease in erythrocyte concentration and therefore in hemoglobin concentration, with a return to normal after delivery. In children the hemoglobin concentration is lower than in adults (Table 3). Violent exercise can produce a transitory decrease of as much as 1 gm. per cent, owing to hemolysis (Orías). Persons on a low economic level have less hemoglobin than the wealthy, probably because of deficiencies in nutrition which cause an insufficient production of hemoglobin.

[1] According to van Slyke *et al.* (*J. Biol. Chem.*, **166**, 121, 1946), 0.4 per cent of total hemoglobin is in the form of methemoglobin, and 1.3 per cent is inactive, as it does not take up O_2 or CO.

[2] The following figures were found in the city of Buenos Aires: young men, 15.3 gm. per cent; young women, 13.38 gm. per cent (Orías, O., *Rev. Soc. argent. de biol.*, **10**, 411, 1930).

There is 34 gm. of hemoglobin per 100 cc. of erythrocytes. In Chap. 3 the absolute and relative values of hemoglobin have been considered.

Carbon monoxide intoxication. Carbon monoxide frequently causes intoxication and death owing to accidents, occupational risks, or suicide. Cases of chronic intoxication have also been observed. This gas is formed by the incomplete combustion of carbon in (*a*) stoves, furnaces, and ovens; (*b*) illuminating gas; (*c*) fires; (*d*) internal combustion engines (automobiles, airplanes); (*e*) gunpowder explosions, etc. There is danger when the gas is allowed to accumulate in small, closed, or badly aired premises.

Death is due to asphyxia because CO displaces oxygen from the hemoglobin in the blood, as its affinity for hemoglobin is 300 times that of oxygen, and carboxyhemoglobin is not an oxygen carrier.[1] When 30 per cent of the hemoglobin is saturated with CO there is headache and vomiting; a 50 per cent saturation endangers life; and a 60 to 70 per cent saturation causes severe intoxication and death. The danger to life depends on the concentration of CO in the air breathed and the time the subject is exposed. Thus a 0.01 per cent concentration of CO is well tolerated during many hours; a 0.05 per cent concentration produces signs of intoxication after a few hours; a 0.1 per cent concentration is dangerous after an exposure of one hour; and a 1 per cent concentration kills in a few minutes.[2]

[1] The dissociation curve of hemoglobin in blood intoxicated by CO is altered by shifting to the left, *i.e.*, HbO_2 will give up oxygen only when the oxygen tension is low (see Chap. 28).

[2] The danger of CO poisoning can be calculated, for the practical purposes of industrial hygiene, by multiplying the concentration of CO per million in the air by the hours of exposure. When the figure is 600 only slight symptoms are observed; at 900 there is headache and vomiting; at 1,500 there is danger of death. A popular way of recognizing the presence of CO in the air, used by miners, is to take a bird or a mouse into the mine; these animals rapidly succumb to CO intoxication. Automatic indicators of CO have been manufactured. They contain Hopcalite, a catalyzer which heats up when CO is oxidated. The heat produced warms a thermocouple connected with an indicator, which gives directly the concentration of CO in the air.

The blood and tissues of subjects intoxicated with CO have a typical scarlet color.

Carbon monoxide in the blood can be estimated by chemical methods or by spectrophotometry. There are two characteristic absorption bands in the spectrum of carboxyhemoglobin (Fig. 10). Carboxyhemoglobin is not easily reduced by reagents that reduce oxyhemoglobin, a fact that has been used to distinguish the former from the latter.[1]

Carbon monoxide can be displaced from hemoglobin by oxygen, if the concentration of the latter is greater, according to the mass law: one part of CO is the equivalent of 210 to 300 parts of O_2.

Carboxyhemoglobin is not an absolutely stable compound; otherwise it would be impossible to treat carbon monoxide poisoning with the usual methods. A person intoxicated by CO should be immediately removed from the contaminated atmosphere. If possible, he should be made to breath oxygen or, better still, a mixture of oxygen and 7 per cent CO_2, which increases pulmonary ventilation and thus accelerates the elimination of CO. Artificial respiration should be kept up until the patient breathes normally. Carboxyhemoglobin can be removed from the blood by bleeding and the hemoglobin renewed with the transfusion of normal blood. An intoxicated person recovers gradually when adequate treatment is given, but if the intoxication has been sufficiently severe, sequelae such as pneumonia and lesions (softening) in the central nervous system can occur.

THE STRUCTURE OF HEMOGLOBIN AND HEMOGLOBIN DERIVATES

It is possible to separate the two components of hemoglobin, heme and natural globin. Hemoglobin owes its color to heme, which is also responsible for its respiratory function. Heme contains ferrous iron (Fe^{++}) and because of this can take up and set free oxygen in the process of oxygenation and reduction of hemoglobin. This reversible process (hemoglobin $\rightleftarrows$ oxyhemoglobin) is called "oxygenation" to distinguish it from the irreversible oxidation of hemoglobin. When irreversibly oxidized heme is converted into hematin, and hemoglobin into methemoglobin; in these compounds there is ferric iron (Fe^{+++}) and they cannot give up oxygen to the tissues for purposes of respiration.

[1] Consult technical manuals.

Protoporphyrin Compounds

The following are the most important compounds of protoporphyrin:

With ferrous iron (Fe^{++}):
- Heme, or reduced hematin
- Hemoglobin, heme + globin
- Oxyhemoglobin, heme + globin + O_2
- Hemochromogen, heme + denatured globin

With ferric iron (Fe^{+++}):
- Hematin, oxidized heme
- Hemin, hematin chlorhydrate
- Methemoglobin, hematin + globin + OH
- Cyanhemoglobin, hematin + globin + CN
Hemochromogens. Compounds of heme and nitrogenous bases, *e.g.*, proteins except natural globins, are called "hemochromogens" (Anson and Mirsky). At first this name was given to the compound obtained by treating hemoglobin with an alkali, or oxyhemoglobin with an alkali and a reducing agent. It is a compound of heme with denatured globin, the molecular weight of which is only 16,800.

Hematin. This is an oxidized heme, in which the ferrous iron (Fe^{++}) has been changed to ferric iron (Fe^{+++}). It can be easily prepared by adding dilute acid to hemoglobin or to oxyhemoglobin; the solution takes on a dark brown color. This reaction is used in several hemoglobinometers.

Hemin. This is hematin chlorhydrate prepared by heating blood with glacial acetic acid and a very small amount of NaCl. It forms crystals known as Teichmann's crystals, which are used in legal medicine to identify blood stains (Fig. 9).

Hemin has been obtained by synthesis,[1] and by uniting it to natural globin, hemoglobin has been synthesized.[2] Globin has not yet been prepared synthetically.

Methemoglobin. This is a compound of hematin (oxidized heme) and natural globin. Like other ferric (Fe^{+++}) compounds of protoporphyrin, it does not set free oxygen in a vacuum, and therefore does not give it up to the tissues. It is usually symbolized as Hb(OH), and can be produced *in vivo* and *in vitro* by the action of nitrites, chlorates, anilin, nitrobenzene, etc. It is formed by the action of potassium ferricyanide on oxyhemoglobin, setting free oxygen. This reaction is used for the estimation of oxyhemoglobin:

$$HbO_2 + (CN)_6Fe^{+++}K_3 + K(OH) \rightarrow (CN)_6Fe^{++}K_4 + Hb(OH) + O_2$$
Methemoglobin is a chocolate brown color; it crystallizes, and its absorption spectrum has a typical band in the red, between the C and D lines, the maximum intensity being at 6302 A. On reduction with sodium hydrosulfite, it is transformed into hemoglobin, which can in turn be oxygenated into oxyhemoglobin. When there is marked methemoglobinemia, the subjects have a permanent blue color (cyanosis) of their skin. Enterogenous cyanosis is due to methemoglobin formed by nitrites originated in the intestine. Methemoglobin is slowly disintegrated in the organism by an enzymatic process, which can be accelerated by glucose and methylene blue (M. Brooks).

Methemoglobin combines with CNH and forms cyanhemoglobin, or rather cyanmethemoglobin. In the treatment of cyanide intoxication, moderate doses of nitrites are given by inhalation of amyl nitrite or intravenous injection of sodium nitrite. The nitrites transform part of the hemoglobin or oxyhemoglobin into methemoglobin, which then combines with the cyanide in the plasma. The concentration of cyanide is thus diminished, and the condition of the patient improves. A still better treatment (Hug) consists in the intravenous injection first of sodium nitrite, which forms methemoglobin, and then of sodium thiosulfate, which is an antidote of cyanide,[3] transforming the latter into the less toxic sulfocyanide.

[1] FISCHER and ZEILE, *Ann. d. Chem.*, **468**, 98, 1929.

[2] HILL, R., and H. F. HOLDEN, *Biochem. J.*, **20**, 1326, 1926.

[3] The antidotic action of thiosulfate on cyanide was discovered by Lang, and later studied by Buzzo.

Catahemoglobin is an oxidated hemochromogen, formed by the union of hematin (oxidized heme) with denatured protein.

PORPHYRINS

Porphyrins form part of the active nucleus of chlorophylls a and b, hemoglobin, myohemoglobin, catalase, peroxidase, and cytochromes.

Glycine is a precursor of heme (Shemin and Rittenberg, 1946) and its derivatives (stercobilin) and other porphyrins (uroporphyrin, coproporphyrin). This has been demonstrated by administering glycine with labeled N (N^{15}) or labeled C, which are traced to the pyrrole nuclei of heme. Acetate is also a precursor of part of the pyrrole molecule.

The following porphyrins have been identified so far in different substances of human origin: protoporphyrin 9, mesoporphyrin 9, deutoporphyrin 9, coproporphyrin I and III, and uroporphyrin I. Porphyrin derives from porphin by substitution of the β hydrogens. Porphin is made up of four pyrrole groups joined by four methinic bridges. Fischer has proposed the following terminology for this group of substances: the pyrrole nuclei are numbered with the Roman numerals I to IV; the β hydrogens of the four nuclei are numbered from 1 to 8 with Arabic numerals; the four CH bridges are named α, β, γ, and δ (formula I). The β hydrogens can be replaced by the following groups: methyl (CH_3), ethyl (C_2H_5), vinyl ($CHCH_2$), a propionic acid residue ($CH_2 \cdot CH_2COOH$), etc. From the number of substituted groups, the number of isomers can be calculated. The different isomeric types are called I, II, III, and IV when the substituted groups have the same relative position as the methyl and ethyl groups of etioporphyrins I, II, III, and IV.

The porphyrin in hemoglobin is protoporphyrin 9 (isomer III). Normally it is found free in small quantities in the erythrocytes and in Harder's gland in rats. Pathologically it can be found in the urine and feces. There is a small amount of free coproporphyrin III in erythrocytes; apparently it is a precursor of protoporphyrin (Watson).

Hematoporphyrin is a laboratory product obtained by the action of strong acids on hemoglobin. In spite of its name it is not the porphyrin in hemoglobin and has never been found in normal or pathologic human tissues or secretions.

A small amount of coproporphyrin is nor-

PORPHIN PROTOPORPHYRIN 9 (type III) HEMOGLOBIN

COPROPORPHYRIN I COPROPORPHYRIN III UROPORPHYRIN I

M = $-CH_3$ (methyl)
V = $-CH{=}CH_2$ (vinyl)
Ac = $-CH_2-COOH$ (acetic acid rest)
P = $-CH_2-CH_2-COOH$ (propionic acid rest)
mally found in the feces (200 to 250 μg daily) and in urine (30 to 80 μg). This is a mixture of coproporphyrins I and III.

The protoporphyrin of the erythrocytes (20 to 40 μg per 100 ml.) increases when there is an intense erythroblastic activity, a deficiency in the utilization of iron, or decomposition of hemoglobin within the erythrocyte.

Porphyrinuria. In certain pathologic conditions the excretion of coproporphyrin in the urine increases; this is known as porphyrinuria. Coproporphyrin I increases when erythropoiesis is abnormally active and in hepatic diseases. Coproporphyrin III is excreted in large amounts in lead poisoning and other intoxications and when there is an infectious condition.

The main porphyrins that have so far been found in man are protoporphyrin 9, mesoporphyrin 9, deuteroporphyrin 9, coproporphyrins I and III, and uroporphyrin I.

Porphyria. This is a disturbance in pyrrole metabolism. There are two main types: (*a*) *congenital porphyria;* (*b*) *acute intermittent porphyria,* including toxic porphyrias produced by certain drugs.

Congenital porphyria is more frequent in males than in females. It appears early in life and has the following signs:

1. Cutaneous lesions due to photosensitivity of the skin provoked by porphyrin.[1] They are situated in areas exposed to light. Reddening and blistering of the skin occur; in extreme cases there is necrosis and mutilation of the extremities.
2. Reddish-brown urine, which becomes red when exposed to the air. It contains large amounts of uroporphyrin I, coproporphyrin I, and other porphyrins. In many cases it has been shown to be transmitted genetically as a recessive character.

Acute intermittent porphyria is more frequently observed in women than in men and is transmitted by heredity. It has the following signs and symptoms:

1. Abdominal pain, constipation, and other digestive disturbances.
2. Muscular weakness, paralysis, and other nervous symptoms.
3. Mental disorders.
4. Usually, dark brown urine, which concontains a mixture of uroporphyrin I with

[1] A subject injected with porphyrins or one who produces porphyrins has no cutaneous alterations if kept in the dark, but the alterations appear when the skin is exposed to light.

other porphyrins. There is also a colorless porphyrinogen.

Bilirubin

Bilirubin is the pigment in human bile; it is also found in blood plasma, which owes its yellow color mainly to this pigment. Normal plasma contains 0.6 (0.4 to 0.8) mg. per 100 cc. It originates in the heme of hemoglobin. Injection of hemoglobin, or of heme, is rapidly followed by an increase in the excretion of bilirubin in the bile. This excretion is also increased when there is intravascular hemolysis. Coupled oxidation of hemoglobin or hematin and ascorbic acid *in vitro* gives rise to green hemochromogen, which is converted to biliverdin; this is then transformed into bilirubin (Lemberg and Legge, 1949). Part of the bilirubin formed (at least 11 per cent) apparently does not derive from hemoglobin (London *et al.*, 1950). Bilirubin is formed partly in the liver and partly outside it.

The extrahepatic origin of bilirubin. Local formation of bilirubin in the tissues has been suspected for many years because of several facts:

1. A yellow color appears where there has been a local extravasation of blood, *e.g.*, bruising of the skin.
2. A long time after blood has been shed into the tissues, crystals are found, which were at first thought to be of a substance called hematoidin, but now have been identified as bilirubin.
3. Jaundice is a prominent symptom in several hepatoses, in which there is extensive degeneration and destruction of liver cells. Therefore the liver must be mainly an organ of excretion of bilirubin, not of its formation.

Mann and Magath gave definite proof of the extrahepatic formation of bilirubin. They removed the liver, or the liver and the intestines, in dogs; 3 to 6 hr. after hepatectomy, the tissues took on a jaundiced aspect, and the concentration of bilirubin in plasma increased.[1] Injection of hemoglobin increased even more the concentration of bilirubin in plasma. The same results have been obtained in eviscerated rats kept alive for 48 hr.

[1] Confirmed by Royer and Cornejo-Saravía (*Compt. rend. Soc. de biol., Paris*, **102**, 424, 1929).

The cells of the reticuloendothelial system, principally in the spleen and bone marrow, are the source of extrahepatic bilirubin. Hemoglobin is taken up by the phagocytes of this system and changed into bilirubin. Mann and his collaborators found more bilirubin in the blood of the splenic vein and in the blood leaving the limbs than in arterial blood. The difference in bilirubin concentration in arterial and venous blood from a limb disappeared when the bones (consequently the bone marrow) were extirpated. Splenectomy alone does not suppress the formation of extrahepatic bilirubin, which continues in other parts of the organism. If the reticuloendothelial system is blocked by the injection of colloid suspensions (*e.g.*, colloidal iron), a transitory decrease in the excretion of bilirubin in the bile occurs.

The hepatic origin of bilirubin. The part played by the liver in the formation of bilirubin has been clearly demonstrated in geese. When they are intoxicated with hydrogen arsenide there is hemolysis, hemoglobinemia, and (later) jaundice. If the liver is removed, jaundice does not occur (Minkowski and Naunyn). The absence of jaundice was attributed to the removal of the hepatic cells, but McNee believes it is due to the suppression by hepatectomy of a large part of the reticuloendothelial system, in this species situated mainly in the liver.

In the dog the injection of toluylenediamine provokes jaundice. Previous removal of the liver reduces jaundice to one-third its intensity (Melchior, Rosenthal, and Licht). From these experiments it has been concluded that in this species two-thirds of the bilirubin is formed in the liver and one-third is of extrahepatic origin.

The double origin of bilirubin, hepatic and extrahepatic, is now universally admitted. Conclusive evidence has not yet been obtained as to (*a*) whether more bilirubin is formed outside the liver (Mann) or in the liver (Rosenthal); (*b*) whether bilirubin is formed in the cells of the reticuloendothelial system (Aschoff-McNee) or mainly in the hepatic cells (Rosenthal).

Direct and indirect bilirubin. Van den Bergh has used diazonium as a reagent for bilirubin.

1. *The direct reaction.* If blood plasma or serum to which the diazoreagent is added gives a violet color in 10 to 30 sec., there is said to be a direct reaction (van den Bergh). This direct reaction is given by

bilirubin which has passed through the hepatic cells.[1] It is obtained with bile; also with blood plasma in those cases of jaundice due to the reabsorption of bile because of an obstacle in the bile ducts, or because of dislocation of the hepatic cells in the course of degenerative or inflammatory processes of the liver.

2. *The indirect reaction.* In this reaction, observed in hemolytic jaundice, alcohol must first be added to the plasma or serum, and then the diazoreagent. The indirect reaction is supposed to be given by bilirubin formed in the reticuloendothelial system without passing through the hepatic cells.

Other differences between direct and indirect bilirubin have been noted: (*a*) direct bilirubin passes through the kidney into the urine; (*b*) indirect bilirubin can be extracted with chloroform. This last is not a definite proof that indirect bilirubin is a different substance, as the extraction is conditioned by the pH in aqueous solutions (Kerppola and Leikola). In plasma the variations in pH do not modify the reaction to any extent, but an increase in phosphatides favors the extraction (López-García and Zelasco). The cause of the direct and indirect reaction is not known. It is supposed that in the first case bilirubin is only absorbed by the serum albumin, while in the second case it forms a compound from which it must be separated by alcohol before it can react with diazonium (Coolidge).

A yellow reaction with diazonium is given by plasma which has a high concentration of urobilinogen (Varela-Fuentes). In patients with jaundice due to obstruction of the bile ducts by gallstones, cancer, or any other obstacle, the serum gives up bilirubin when extracted with ether (ether-soluble bilirubin).

Jaundice. When there is an abnormally high concentration of bilirubin in the plasma, the skin and mucosa take on a yellow color (jaundice) and the urine becomes yellow. Jaundice has been classified into (*a*) *prehepatic jaundice* of hemolytic and other origins (among the hemolytic varieties there is *hemolytic jaundice*, with increased fragility of the erythrocytes); (*b*) *hepatic jaundice*, due to lesions in the hepatic cells or canals caused by intoxication or infection (the vulnerable point of the bile canals is the ampulla where the intercellular spaces join the ducts that have a differentiated wall [Eppinger]); (*c*) *obstructive jaundice*, also called *posthepatic jaundice* (Ducci), which is due to reabsorption of bilirubin into the blood and lymph because of an obstacle in the bile ducts.

[1] According to the classical conception extrahepatic bilirubin is taken up by the Kupffer cells and then passed to the liver cells, which modify it and excrete it into the bile ducts.

In certain species, *e.g.*, the toad, *Bufo arenarum*, bile contains only biliverdin, which gives an olive green color to the plasma when it accumulates in the blood (Cabello, 1943); "chloricia" would be the appropriate name for this type of jaundice. In mammals biliverdin has never been found in the plasma.
FIG. 11. Origin and cycle of urobilin. 1, normal route, intestine-liver-blood-kidney; 2, origin in infected gall bladder; 3, small quantity to and from the tissues.

STERCOBILIN AND UROBILIN

When bile reaches the intestine, bilirubin is converted into stercobilinogen by the action of the intestinal bacteria. Stercobilinogen when oxidized gives stercobilin. Watson has obtained crystallized stercobilin from feces (1932) and urine (1933).

Bilirubin is converted by a process of reduction into mesobilirubinogen, which may then follow one of three main paths (Watson):

1. It is converted into L-stercobilinogen by the simultaneous action of bile and feces; L-stercobilinogen is then oxidized into L-stercobilin.
2. If there is no bile, it is converted by the feces into urobilin IXα. This can also be done *in vitro* by a process of reduction (Siedel, 1936).
3. In bile contaminated by bacteria it is converted into D-urobilin. Stercobilin and the different urobilins can be identified by the green fluorescence they give out in the pres-

ence of zinc salts (Jaffé, 1868). Stercobilinogen and urobilinogen in the presence of *p*-dimethylaminobenzaldehyde give a red color; this reaction (Ehrlich's reaction) is used for quantitative determination of these substances.

The amount of stercobilinogen and stercobilin in the feces is dependent mainly on the amount of bilirubin that reaches the intestine. If bile is prevented from arriving into the intestine, there is no bilirubin or stercobilinogen in the feces, and no urobilin in the urine.

Certain bacteria are of fundamental importance in the formation of stercobilinogen. Thus, if aureomycin is administered in doses such that the intestinal contents become free from coli bacilli, stercobilinogen disappears from the feces, bile, and urine.

At least 15 to 30 per cent of stercobilin does not come from hemoglobin in the erythrocytes. When glycine labeled with N^{15} is given, it can be traced to stercobilin almost immediately and not only after an interval of 100 to 125 days, as would be the case if it were first incorporated into hemoglobin and appeared in stercobilinogen only after disintegration of the erythrocytes (London *et al.*, 1949). It seems that in pernicious anemia a larger proportion of stercobilinogen is originated in this way.

Intestinal stercobilinogen and stercobilin[1] follow two paths: (*a*) up to 85 per cent is partially disintegrated and excreted in the feces (40 to 280 mg./day, measured as stercobilinogen); (*b*) the rest is reabsorbed by the intestinal mucosa and taken by the portal blood to the liver (Fig. 11). If the liver is functioning normally most of the stercobilin is retained, and its structure is modified by chemical processes not yet well understood. A very small amount that is not retained by the liver passes into the blood and is distributed throughout the body. Its presence in the blood has not been demonstrated by analytic methods, but there is indirect evidence of its existence. In diseased persons it has been found in the blood and its amount measured. It is finally excreted by the kidney as stercobilinogen (urobilinogen), which by oxidation is converted into stercobilin (urobilin). The total amount eliminated daily is not more than 0.6 mg. Very small amounts have been found in tissues (Royer).[1]

[1] This term will cover stercobilin and stercobilinogen. The latter is more abundant; from 50 to 200 mg. is excreted daily in human feces (Royer).

Müller formulated in 1892 the so-called "enterohepatic theory," *i.e.*, that stercobilinogen (urobilinogen) is formed in the intestine and reabsorbed in part. Most of this is retained by the liver, the remainder being eliminated by the kidney. For this reason urobilin diminishes and finally disappears from the urine of patients with an obstruction in the common bile duct; it reappears if these patients are given bile by mouth. Experimental proof of this theory is now available.

The biliary origin of urobilin can be demonstrated by making a biliary fistula in a dog, so that bilirubin cannot pass into the intestine. After a few days stercobilin disappears from the feces and urobilin from the urine, the tissues, and the bile (Royer and Cornejo-Saravía). The introduction of bile or bilirubin into the intestine is followed by the reappearance of stercobilin in the feces and urobilin in the urine.

The liver plays an important part in retaining and regulating the excretion of these substances. A few hours after hepatectomy, stercobilin can be found in the blood plasma, where it increases progressively. This is due to its absorption from the intestine and the absence of retention by the liver. The intestinal origin can be easily demonstrated: a biliary fistula is made and hepatectomy is not performed until the feces contain no more stercobilin; in this case there is no accumulation of stercobilin in the blood. If bile or stercobilin is introduced into the intestine, it appears in the blood (Royer and Cornejo-Saravía).

The capacity of the liver to retain stercobilin can be demonstrated by injecting this substance into the portal vein and estimating it in the blood of the suprahepatic veins. This capacity diminishes considerably when the liver is damaged by some toxic substances, *e.g.*, chloroform (Royer).

An increase in urobilinogen and urobilin in the urine is a sign of hepatic insufficiency (Royer, Watson, López-García). Urobilinuria also increases when there is an excessive destruction of erythrocytes (pernicious anemia, injection of hemolytic substances). In an infected gall bladder, part of the bilirubin of the bile is transformed into urobilin by bacterial

[1] Jaffé discovered urobilin in 1869. Urobilinogen was identified as mesobilirubinogen by Fischer and Meyer-Betz (1917). Crystallized stercobilin was prepared by Watson from feces (1933) and urine (1934). Seiden and Meyer obtained urobilin IXα by synthesis.

activity (Royer, López-García), and the latter increases both absolutely and relatively to bilirubin.

CHAPTER 5

The Life of the Erythrocytes

THE FORMATION OF the blood cells is known as hemopoiesis. Erythropoiesis is the formation of the red blood cells, leukopoiesis that of the white blood cells, and granulopoiesis that of the polymorphonuclear granulocytes.

EMBRYONIC AND FETAL ERYTHROPOIESIS

Three stages can be distinguished in the development of the erythrocytes in the embryo and fetus: (*a*) mesoblastic; (*b*) hepatic; (*c*) myeloid. Each one of these stages is predominant during 3 months of intrauterine life, and the passage from one to another takes place gradually.

The mesoblastic period begins in the early stages of embryonic development. All the blood cells originate in the totipotential embryonic mesenchyma. Vascular islets (Wolff and Pander) are formed in the extraembryonic structures, on the mesenchyma of the yolk sac; blood vessels and erythrocytes are formed in these islets. The vascular areas join up with each other to form a network, which is later connected with the chorion and with the heart. The islets of Wolff and Pander are at first compact columns of cells but later the peripheral cells flatten out and become primitive endothelial cells, while those in the center of the column take on a rounded shape and are separated from each other by a primitive plasma. These free cells (erythroblasts) are large nucleated cells. If they become prematurely loaded with hemoglobin, they give rise to large nucleated erythrocytes. Primitive erythrocytes are also formed by proliferation of the endothelial cells, at first in the extraembryonic vascular areas and later within the embryo. Finally the circulating cells also multiply and form primitive blood cells. This type of development is seen between the third and sixth week of embryonic life, begins to diminish in the second month, and has ceased completely by the fourth month.

The hepatic stage commences in the course of the second month of embryonic life, but it is not fully developed until the third month, when the liver becomes the principal organ of erythropoiesis; later the spleen also takes part in this process. The liver produces normocytes, *i.e.*, nonnucleated red cells of normal size. From the third month onward, only 8 per cent of the erythrocytes have a nucleus.

In the myeloid stage erythropoiesis takes place mainly in the bone marrow. This stage begins during the second month and develops in the course of the fifth month, and as the liver loses importance the bone marrow gains it. During the last three months of fetal life, the bone marrow becomes the principal site of erythropoiesis.

ERYTHROPOIESIS IN THE ADULT

After birth, in man, erythropoiesis is carried out exclusively in the bone marrow; in normal conditions no erythrocytes are formed in the liver and the spleen.

There are two theories as to the origin of the blood cells: the unicist (monophyletic) and the pluralist (polyphyletic) theories. The former maintains that the mesenchyma gives rise to a primitive blood cell, called hemocytoblast (Ferrata), lymphoidocyte (Pappenheim), myeloblast (Naegeli), etc., from which all the blood cells arise. There are two main pluralist theories:

1. The dualist theory postulates the existence of a myeloid series of cells produced in the bone marrow, in which a primitive cell gives rise to the erythrocytes and the granulocytes; a second series of lymphoid cells is produced in the lymphatic organs and gives rise to the lymphocytes and monocytes.
2. Schilling has proposed a theory in which the blood cells have three different origins: a

myeloid series of cells produces erythrocytes and granulocytes; lymphocytes and monocytes have each a separate source.

Table 5 gives the principal stages in the development of the different adult blood cells.[1]

Table 5. Hemocytopoiesis in Adult Man

Mesenchymatic cell in hemopoietic tissues

Lymphoid organs	Reticuloendothelial system	Myeloid tissue			
		Myeloblast	Megakaryoblast	Proerythroblast	Promegaloblast†
Lymphoblasts				Basophil erythroblast	Basophil megaloblast
	Monoblast	Promyelocyte			
Prolymphocyte		Myelocyte		Polychromatophil erythroblast	Polychromatophil megaloblast
Lymphocyte	Monocyte	Metamyelocyte	Megakaryocyte	Orthochromatic normoblast	Orthochromatic megaloblast
		Granulocyte*	Thrombocytes	Erythrocyte	Macrocyte

* There are three series of myelocytes: neutrophils, eosinophils, and basophils, which give rise to the corresponding type of granulocyte.

† This series appears only when there is insufficiency of the hematinic or antianemic principle, which is necessary for the normal maturation of the erythroblasts.

In the development of the erythrocytes several stages can be differentiated. The primitive hemocytoblast gives rise to a proerythroblast,[2] the precursor of the erythroblasts. This is a nucleated cell with a strongly basophil protoplasm, which gradually loses its basophilia, and after passing through a polychromatophil stage, becomes acidophil (orthochromatic) like the adult erythrocyte and is called a normoblast. The nucleus shrinks and then disappears by extrusion from the cell, although some observers maintain that it is dissolved (karyolysis). In certain pathologic conditions the nucleus breaks up into fragments (karyorexis) and then disappears.

[1] The sum of the circulating erythrocytes and the erythroid cells of the bone marrow has been called the "erythron" (Boycott) or "erythrocytic organ." Its total volume is about 1,500 cc. in the adult.

[2] Sabin and Doan have given the name of "megaloblast" to the proerythroblast. Previously Ehrlich had given this name to a cell found only in pathologic cases (pernicious anemia, lack of erythroblastic maturation factor); this is a large cell with a nucleus of typical structure, which has a delicate chromatin network. The name of megaloblast should be given only to this abnormal cell.

Reticulocytes. Young erythrocytes still have some basophilic substance, which is evident either as polychromasia or in the form of a fine basophilic reticulation of the cytoplasm (Cesàris Demel); these cells are known as reticulocytes. The reticulation can be revealed by supravital staining of the fresh erythrocytes with cresyl blue, which precipitates the basophilic substance; if a blood smear is then made, it can be further stained with the usual dyes.

Normally 0.5 to 1.5 per cent of the erythrocytes are reticulocytes. The proportion is greater when erythropoiesis is stimulated, *e.g.*, during the period of blood regeneration after hemorrhage, in the polycythemia of high altitude, and in hemolytic jaundice. The increase in reticulocytes is a valuable sign of improvement in pernicious anemia, and serves as a guide in the treatment of this disease with liver extracts, as it precedes the increase in erythrocytes (Fig. 14).

Bone marrow. The total amount of bone marrow in the body weighs from 1.5 to 3.5 kg. It has the following functions:

1. The formation of erythrocytes (erythropoiesis).

2. The formation of granulocytes (granulopoiesis).
3. The formation of thrombocytes.
4. The destruction of erythrocytes.
FIG. 12. Activity of bone marrow at different ages. The curves of the shaft of the fibula, radius, and ulna are similar to that of the tibia; that of the humerus is similar to that of the femur.

The bone marrow can develop a considerable erythropoietic activity, and in two weeks it can produce several times its weight of erythrocytes (Whipple). In infancy and when there is an increased erythropoietic activity, the bone marrow has a red color. From puberty onward the marrow in the shafts of the long bones of the limbs becomes loaded with fat, takes on a yellow color, and has little or no erythropoietic activity; this process is completed by the twentieth year of life Hemopoiesis continues throughout life in the marrow of the vertebrae, sternum, ribs, pelvis, and bones of the skull (Fig. 12). The hemopoietic activity of the bone marrow can be examined by making a smear of a sample obtained by puncture of the sternum.[1]

There is still doubt as to whether the erythrocytes are formed outside the blood vessels or in closed sinusoids.

THE REGULATION OF ERYTHROPOIESIS AND THE FORMATION OF HEMOGLOBIN

The most important quantitative data on the erythrocytes are

1. The concentration, or number of erythrocytes per cubic millimeter.
2. The total amount in all the blood in the body, given in liters or in cubic centimeters.
3. The relative volume in 100 cc. of blood, measured by the hematocrit.

Variations in the concentration of erythrocytes can be due to

[1] Pianese, 1903; Ghedini, 1908; Seifarth, 1923.

1. Hemoconcentration produced by loss of water from the plasma (profuse sweating, diarrhea, vomiting, polyuria, shock, etc.), or by loss of plasma (burns).
2. Dilution of the blood.
3. Sudden mobilization of the erythrocytes in the spleen and other blood stores.

The total number of circulating erythrocytes is the result of a dynamic equilibrium between their formation and destruction. A temporary alteration of this equilibrium can be brought about by the sudden outpouring of erythrocytes into the circulation by contraction of the spleen, or inversely by the storage of erythrocytes in blood reservoirs. The equilibrium between formation and destruction of erythrocytes is fairly constant. Variations in the number of erythrocytes are seldom greater than 300,000 and exceptionally 500,000 on the same day, and the erythrocyte count of an individual determined on different days gives a fairly constant figure. The loss of erythrocytes by hemorrhage is replaced in a few days or weeks by an increased production until the normal concentration is reached.[1] On the other hand, if erythrocytes are injected so as to increase their concentration, the number in excess is destroyed until the normal concentration is restored.

Formation of the stroma. Apparently there is never a lack of raw materials necessary for the production of the red cell stroma, such as nucleoproteins, globulins, phosphatids, cholesterol, and minerals.

Proteins and the regeneration of hemoglobin. A normal diet must provide a sufficient amount of high-quality protein to maintain a normal concentration of hemoglobin and plasma proteins. Whipple, Hooper, and Robscheit[2] have studied the regeneration of hemoglobin in dogs. The animals were submitted to repeated hemorrhages, so as to diminish the concentration to 30 per cent of the normal value. In the interval between two bleedings the protein under consideration was given in the food or injected, and the amount of hemoglobin regenerated was measured. Hemoglobin regeneration was accelerated by several proteins

[1] In some cases erythropoiesis is stimulated by moderate hemorrhage, and the erythrocyte count is increased above the initial level.

[2] *J. Exper. Med.*, 77, 375, 1943; *Nutrition Rev.*, 1, 284, 1943.

and amino acids.[1] Excellent results were obtained when the following substances were given by mouth: liver, kidney, meat, or amino acids. The same results are obtained by injection of blood plasma, hemoglobin or globin, or the product of digestion of these proteins or of caseinogen. A mixture of the amino acids indispensable to maintain the body weight gives rise to the formation of great amounts of hemoglobin and plasma proteins. On a carbohydrate diet (bread and sugar) there is not much regeneration of hemoglobin. The liver plays a direct or an indirect part in the utilization of food for hemoglobin regeneration. Glycine contributes to make up a large part of the pyrrole constituent of porphyrins and heme.

Iron. Nearly all the iron in the blood is found within the erythrocytes, forming part of the hemoglobin molecule. In 100 gm. of hemoglobin there is 0.34 gm. of Fe, about 50 mg. in 100 cc. of blood, and 2 to 3 gm. in all the blood of an adult; the total amount of iron in the body is from 3 to 4 gm. There is only 0.12 to 0.14 mg. of iron in 100 cc. of plasma.[2] There are iron reserves in the bone marrow, the liver, and the spleen. A crystallized protein containing 20 per cent iron has been obtained from these organs; it is called ferritin. These reserves are important in infancy; they prevent breast- or bottle-fed babies from having a decrease in the hemoglobin concentration of the blood in spite of the fact that milk has very little iron.

The diet should provide 10 to 12 mg. of iron daily, and 15 mg. in the case of pregnant women. Inorganic iron, especially ferrous iron, is well absorbed and utilized, better than organic combinations of iron. The principal factor in the regulation of iron absorption is the amount of iron in the body. If there are abundant reserves, little is absorbed; if they are low, more is absorbed (Whipple *et al.*).[3] Absorption of iron increases during pregnancy and is favored by vitamin C. An excess of alkali, of phytate (brown bread, oats), or of phosphate in the diet diminishes the absorption of iron, because part of it becomes insoluble (see Chap. 45, Mineral Metabolism).

Iron deficiency causes hypochromic microcytic anemia. In this type of anemia, but not in others, iron treatment gives good results.[1] Anemia due to iron deficiency may be caused by a prolonged exclusive milk diet or by chronic hemorrhages. Iron deficiency is an important factor in the anemia produced by hookworm (*Necator* or *Ancylostoma*); usually it can be prevented by a meat diet (Fulleborn) and is improved by iron treatment (Oswaldo Cruz, Jr.).[2]

[1] *J. Exper. Med.*, **81,** 171, 1945; **85,** 243 and 267, 1947.

[2] Powell, J. F., *Quart. J. Med.*, 13 (49), 19, 1944.

[3] Balfour, W. M., *et al.*, *J. Exper. Med.*, **76,** 15, 1942; Hahn, P. F., *et al.*, *J. Exper. Med.*, **78,** 169, 1943.

Copper. White rats fed exclusively on cow's milk suffer from a fatal type of anemia. Iron treatment does not improve the condition of these animals, but if copper is added to the iron treatment, hemoglobin is normally regenerated and the animals are cured.[3] Copper deficiency is unknown in man; if copper is an indispensable element, sufficient amounts are provided in food and water. Copper treatment has not improved the result of other treatments in human anemias. Human serum has 0.11 mg. per cent copper in man and 0.13 mg. per cent in woman.

Oxygen tension. A very important factor that regulates erythropoiesis is the partial pressure of oxygen in the atmosphere. A decrease in oxygen pressure stimulates erythropoiesis; an increase has an inhibitory or moderating effect. The stimulating effect of low oxygen tension was first observed by Viault (1889), who found an increase in the concentration of erythrocytes in the blood of persons living in the high mountains of Peru; this is known as high-altitude polycythemia.[4] The same fact has been observed in the blood of the inhabitants of many cities situated at high altitudes in Peru, Bolivia, and Mexico. The increase in erythrocyte concentration is proportional to the height above sea level (Table 6). There is an increase in the concentration and in the total amount of erythrocytes. In the course of a rapid ascent in an airplane, at first there may be simply a transitory increase in the concentration of erythrocytes, due to contraction of the spleen provoked by anoxia, emotion, or muscular effort, and thus stored erythrocytes are sent into the circulation. When the subject remains at high altitude for some time, there is an increase in the formation

[1] Hahn, P. F., *Medicine*, **16,** 249, 1937; Heath, C. W., and A. J. Pathek, *Medicine*, **16,** 297, 1937.

[2] Cruz, W. O., Jr., and R. P. de Mello, *Mem. Inst. Oswaldo Cruz*, **42,** 401, 1945.

[3] Elvehjem, C. A., *Physiol. Rev.*, **15,** 471, 1935.

[4] The term "hyperglobulia" was used at first, but it should be abandoned as it does not indicate clearly whether there is an increase in the number of the erythrocytes or in their size.

of erythrocytes, preceded by an increase in reticulocytes. There is also an increase in hemoglobin production and in the total amount of hemoglobin in the body. More hemoglobin is, therefore, destroyed, and bilirubin and stercobilin increase (Merino, 1950).
FIG. 13. Antianemic or hematinic factor.

An increase in oxygen tension, produced experimentally by keeping animals in chambers where the atmosphere has been modified by increasing the concentration of oxygen, diminishes the concentration of erythrocytes.

Erythroblastic maturation factor. This factor is also known as the antianemic or hematinic factor. When there is a deficiency of this factor a typical deviation of erythropoiesis occurs; megaloblasts, which develop into megalocytes, are formed instead of normoblasts, which develop into normocytes. This is observed in pernicious anemia and in other macrocytic anemias related to this disease. In pernicious anemia (also called "Addison's" or "Biermer's" anemia) there are megaloblasts in the bone marrow, with production of megalocytes. Therefore, there is anemia, with megalocytes in the circulating blood. Apparently there is also an increased destruction of erythrocytes, as there is an increase of iron and bilirubin concentration in plasma, and an increase in the excretion of stercobilin. There is no hydrochloric acid in the gastric juice (achlorhydria), and after a time severe lesions in the spinal cord are observed. The disease was fatal within a short time until Minot and Murphy (1926) showed that ingestion of liver or kidney in large quantities produced a remission of the disease. Later it was shown that desiccated defatted hog stomach had the same effect. The preparation of very active liver extracts which could be injected has been an important advance in the treatment of pernicious anemia (Gänsslen, 1930).

Castle (1929)[1] observed that if gastric juice and meat are incubated the hematinic principle is formed. This factor would therefore be the result of the interaction of two others, an extrinsic and an intrinsic factor (Fig. 13). The extrinsic factor is found in meat, yeast, etc., and is destroyed by heating. It is vitamin B_{12}. The intrinsic factor is formed in the gastric and duodenal mucosae. By the interaction of the two factors in the stomach and intestine, the antianemic factor is absorbed and stored in the liver, from which it goes to the bone marrow to stimulate normal maturation of erythroblasts and normocytic erythropoiesis.

In pernicious anemia there is deficiency of the intrinsic factor; the extrinsic factor may be found in the intestine. Treatment with liver,

[1] CASTLE, W. B., and MINOT, G. R., "Pathological Physiology and Clinical Description of the Anemias," Oxford, New York, 1936; MINOT, G. R., and M. B. STRAUSS, *Vitamins & Hormones*, **1**, 269, 1943.

stomach, or concentrated preparations of the antianemic factor provokes a marked increase in the reticulocytes, which can make up 10 to 40 per cent of the circulating red blood cells; later normal erythrocytes increase, and the normal concentration of red cells is restored in one to two months (Fig. 14). In cases with a less marked anemia, reticulocytosis is also less marked, although the erythrocyte count increases. The potency of an extract is measured by its effects on patients with pernicious anemia.

A deficiency in the antianemic factor can be caused in several ways: (*a*) by the absence of the extrinsic factor in the diet (tropical anemias, pellagra); (*b*) by deficiency in the intrinsic factor (pernicious anemia, gastric cancer, total or subtotal gastrectomy, pellagra); (*c*) by deficient intestinal absorption (chronic enteritis, sprue, pellagra, infestation by *Diphyllobotrium latum*); (*d*) by deficient storage in the liver (extensive chronic lesions of the liver); (*e*) by deficiency in the response of the bone marrow to the antianemic factor (exceptional cases of myxedema).

Folic acid. This vitamin, so called because it was first obtained from spinach leaves (also called folacine, or *Lactobacillus casei* factor), is one of those in the B complex (see Chap. 49). Its deficiency produces in several species an anemia that is cured by treatment with folic acid. It has the biological and chemical properties of pteroylglutamic acid, and synthetic pteroylglutamic acid has its effect. It exerts a powerful therapeutic activity in certain macrocytic anemias caused by deficient diets. It provokes first an increase in reticulocytes, then an increase in erythrocytes and hemoglobin concentration. It does not, however, prevent the development of neurologic disorders seen in pernicious anemia; therefore it should not be used alone in treatment of this disease.

Certain substances chemically related to pteroylglutamic acid, *e.g.*, 4-aminopteroylglutamic acid (aminopterin), are known as folic acid antagonists, because they inhibit the effects of folic acid and provoke symptoms of folic acid deficiency. Folic acid is converted into the citrovorum factor (CF),[1] or folinic acid, by liver tissue, a process which is inhibited by folic acid antagonists.[1] CF can replace folic acid; it has antianemic activity, and is much more potent in the reversal of the effect of folic acid antagonists. CF is the prosthetic group of a coenzyme essential for the transference of formate,[2] a chemical step of importance in the synthesis of purines and thymine in nucleic acids, also of serine, choline, and methionine.[3] Thymine has antianemic activity if given in large doses.
FIG. 14. Effect of liver extract in a case of pernicious anemia.

Vitamin B_{12}. This substance has been found in liver extracts; it forms red crystals which contain cobalt. It was first identified in 1948 by its antianemic properties (Smith *et al.*) and as a growth factor for *Lactobacillus lactis* Dorner (Rickes *et al.*). It is not toxic and exerts its physiologic effects at very small doses; 0.5 to 1 μg is the amount required daily by a normal adult man. Doses of 10 to 150 μg have produced complete remission in cases of pernicious anemia. Reticulocytes increase first, then the erythrocytes and hemoglobin concentration. Megaloblasts and megalocytes disappear from the blood and bone marrow, and the erythrocyte count returns to the normal level. Lesions on the tongue are healed, and neurologic disturbances are either prevented or, when already established, cured if they are of only moderate severity. Vitamin B_{12} is not active when given by mouth

[1] Sauberlich and Baumann (*J. Biol. Chem.*, **176**, 165, 1948) discovered a factor necessary for the growth of *Leuconostoc citrovorum* (hence its name) which was found in liver extracts and in yeast.

unless gastric juice is administered simultaneously,[1] as occurs with Castle's extrinsic factor. It has been found in the feces in cases of pernicious anemia; probably it is not absorbed owing to deficiency of gastric intrinsic factor. Serum from normal subjects or from patients with pernicious anemia treated with B_{12} ripens megaloblasts into normoblasts *in vitro*, but neither vitamin B_{12} nor normal gastric juice separately has this effect. The hemopoietic factor in normal serum is formed by the interaction of vitamin B_{12} (Castle's extrinsic factor) with a gastric intrinsic factor, which is deficient in pernicious anemia, or with an extragastric intrinsic factor, which accounts for the formation of the hemopoietic factor found in the serum of patients with pernicious anemia who have been treated by injections of vitamin B_{12}.[2]

Vitamin B_{12} has been found in liver, muscle, milk, etc., but in order to obtain large amounts it is usually extracted from culture mediums fermented by *Streptomyces griseus*. Apparently this vitamin plays a part in the synthesis of proteins, nucleoproteins, and thymidine, especially in nuclear metabolism (see Chap. 49, Vitamins).

Vitamin B_{12} is usually far more potent than folic acid, but a few cases of megaloblastic anemia (acute macrocytic anemia of children, etc.) respond to treatment with folic acid, but not to treatment with vitamin B_{12}. Pernicious anemia following gastrectomy usually responds less to treatment with vitamin B_{12} than to that with folic acid.

Other nutritive and endocrine factors. Erythropoiesis and the formation of hemoglobin are conditioned by many nutritive factors. Deficiency of several vitamins (ascorbic acid, niacin, riboflavin, pyridoxin, etc.) provoked experimentally produces anemia. Anemia is also observed in patients suffering from scurvy, pellagra, or ariboflavinosis.

There is a more or less severe decrease in erythropoiesis in several endocrine disturbances such as hypophyseal, thyroid, and adrenal insufficiencies. Testicular hormones stimulate erythropoiesis, while ovarian hormones have a slight inhibitory effect. Polycythemia of unknown origin is observed in some cases of hyperfunction of the adrenal cortex and in experimental lesions of the diencephalon.

THE LIFE SPAN OF THE ERYTHROCYTE

The average life of the erythrocyte has been estimated in several ways. Erythrocytes from a donor of a different, but compatible, group are transfused into a recipient, and the survival of these foreign erythrocytes is determined by repeated isoagglutination tests. The same procedure can be followed using erythrocytes with radioactive iron in their hemoglobin. These injected cells live from 25 to 150 days; most of the observers who have published their results recently agree that the average life of the erythrocyte is 120 days.

The destruction of the erythrocyte. Red cells are being continuously destroyed. Probably they split up into several fragments which are picked up by the cells of the reticuloendothelial system. The proteins and iron of the erythrocyte are stored and used for the formation of new erythrocytes. A great part of the heme in hemoglobin is transformed into bilirubin, about 40 mg. in each gram of hemoglobin (Whipple). For a daily excretion in the bile of 500 mg. of bilirubin, 12.5 gm. of hemoglobin would have to be destroyed; this corresponds to the hemoglobin in 80 cc. of blood. According to other estimates, the amount of hemoglobin destroyed daily varies from 5.5 to 25 gm. The amount of erythrocytes destroyed can be estimated by (*a*) the quantity of bilirubin excreted in the bile and to some extent by the concentration of bilirubin in the blood or its excretion in the urine; (*b*) by the quantity of stercobilin excreted in the feces.

In cases of marked destruction of hemoglobin, a pigment called hemosiderin accumulates in the liver, the spleen, and other organs. It contains up to 17 per cent iron and gives the prussian blue reaction.

FUNCTIONS OF THE SPLEEN

Up to quite recently the spleen was considered to be an enigmatic organ, but now several of its functions are known. It is not indispensable to life, as it can be removed without causing any important disturbance; its functions are either dispensable or carried out by other tissues.

The following structural features are important: (*a*) it has lymph nodes (malpighian bodies) around the arterioles; (*b*) its veins are connected with venous sinuses and clefts in the splenic pulp; (*c*) there are many phagocytic

cells belonging to the reticuloendothelial system in the splenic pulp; (*d*) the blood comes into intimate contact with the cells of the red pulp.

The spleen as a store or reservoir of blood. In normal conditions the spleen is mainly a reservoir of erythrocytes. The arteries open into the sinuses and clefts in the splenic pulp, which is like a sponge in the meshes of which the erythrocytes are stored and from which they can be ejected later into the venous sinuses. The dilatation and contraction of the spleen is due to its plain-muscle fibers, which are stimulated and inhibited by nerve impulses and by humoral factors.

In some animals the relaxed spleen can contain from 15 to 30 per cent of the blood volume. In the cat and the dog the spleen can contract and relax considerably. In man the spleen is not so important a reservoir as in other animals. To estimate the capacity of the spleen as a blood reservoir, the concentration and total amount of erythrocytes in the circulating blood are measured before and after provoking splenic contraction. Contraction of the spleen has been studied in dogs by the following methods:

1. Small metal bands are clipped on the edges of the spleen, and after the animal has recovered from the operation, changes in the size of the spleen can be followed by taking a series of x-ray pictures.
2. The spleen is placed in a plethysmograph which is left permanently in the abdomen.
3. The spleen is "exteriorized," *i.e.*, taken out aseptically from the abdomen and fixed to the body wall, keeping it protected by a suitable bandage, which is removed in order to observe and measure the changes in its size.

These methods allow the survival of the animals in good condition indefinitely and the observation of the size of the spleen in many physiologic conditions without the use of anesthesia.

Several factors produce rapid contraction of the spleen: (*a*) anoxia due to lack of oxygen, asphyxia, anesthesia, high altitude, or CO intoxication; (*b*) hemorrhage; (*c*) muscular exercise; (*d*) cold; (*e*) emotions and reflexes; (*f*) adrenaline; (*g*) estrus and pregnancy. This contraction is caused mainly by nerve impulses, but humoral factors can also induce it; the denervated spleen contracts when there is a sudden discharge of adrenaline from the adrenal gland, or of sympathin into the blood.

The sudden emission of the erythrocytes deposited in the spleen produces a rapid but transitory increase in the concentration and total volume of erythrocytes in the circulating blood. In splenectomized subjects the increase in erythrocytes provoked by emotion, muscular exercise, or the injection of adrenaline is not so great as in normal subjects; such increase as is observed in these cases is due to the evacuation of other reservoirs or to the loss of plasmatic fluid from the blood.

Hemopoietic function. During fetal life erythrocytes and leukocytes are formed in the spleen. In the normal adult erythrocytes are not produced in the spleen, but this organ has a slight effect on erythropoiesis, which can become very marked in certain pathologic states. Lymphocytes are formed in the malpighian bodies of the spleen, and monocytes in the reticuloendothelial system, but granulocytes are not produced.

In certain pathologic states, foci of myeloid tissue appear in the spleen. In these foci, erythrocytes and granulocytes are formed.

In cases of purpura hemorrhagica with a diminished platelet count (thrombocytopenia), the following signs are observed: (*a*) hemorrhages in the skin and mucosae, and fragility of the capillaries; (*b*) lengthening of the bleeding time; (*c*) decrease in the platelet count; (*d*) failure of the clot to retract after coagulation; (*e*) decrease in granulocytes (neutropenia). Splenectomy causes an immediate increase in the platelets, and capillary fragility disappears. Many patients are greatly improved by this operation. Two interpretations of these facts have been given: (*a*) there is excessive destruction of the platelets by the spleen; (*b*) the spleen secretes an excess of a humoral factor (hypersplenia) which inhibits the output of platelets into the circulation. There is an increase of megakaryocytes (the platelet-producing cells) in the hemopoietic tissues, which is considered as a compensatory reaction by those who sustain the first of these theories, and as the result of an arrested maturation and liberation of the platelets by those who admit the second.[1]

Phagocytic function. The spleen forms part of the reticuloendothelial system. The large cells of the splenic pulp, called histiocytes or macrophagocytes, ingest cells, parasites, worn-

[1] Dameshek, W., and E. B. Miller, *Blood*, 1, 27, 1946.

out erythrocytes, and substances in colloidal dispersion such as hemoglobin. After splenectomy the macrophagocytes in the lymph nodes, liver, and bone marrow become hypertrophied, as well as other lymphoid structures, and splenoid tissue can appear in the lymph nodes and liver.

Destruction of erythrocytes and production of bilirubin. There is no proof that normal erythrocytes undergo phagocytosis in the spleen; but worn-out erythrocytes, those damaged by toxins, hemolysins, or infections, and especially the spherocytes of hemolytic jaundice are captured and destroyed by the splenic phagocytes. After having been deposited for some time in the splenic pulp, some of the erythrocytes have an increased fragility in hypotonic solutions (Banti). Moreover splenectomy diminishes the fragility of the erythrocytes. Botazzi has called this function of capturing and destroying fragile erythrocytes the "hemocatheretic" function of the spleen.

In congenital hemolytic jaundice splenectomy diminishes anemia, jaundice, and the fragility of the red cells. This effect is attributed to the removal of an organ that destroys the erythrocytes, especially the spherocytes.

The spleen, because of its erythrocyte-destroying function, is one of the sites where extrahepatic bilirubin is formed (Mann); this is sometimes called the "biligenic" function of the spleen.

Storage functions. The spleen can store cells, parasites, bacteria, and several chemical substances. When there is an excessive destruction of erythrocytes and hemoglobin, a dark brown pigment, called hemosiderin, is formed; it has a large proportion of iron and gives the prussian blue reaction with potassium ferrocyanide in chlorhydric medium. The normal spleen is one of the stores for iron; ferritin, a crystallized protein with 20 per cent iron, has been obtained from splenic tissue. This store is of special importance for sucklings, as milk contains very little iron.

Abnormal storage (thesaurosis) is observed in certain pathologic conditions. In Gaucher's disease the splenic cells store cerebrosides, and therefore great quantities of kerasine. In Niemann-Pick's disease these cells have a foamlike aspect, due to stored phosphatides. Storage of parasites is observed in malaria and leishmaniasis. Ascoli injected adrenaline in chronic cases of malaria so as to produce contraction of the spleen and the expulsion of the parasites into the circulation, where they could be destroyed by adequate doses of quinine.

Functions in infection and immunity. The spleen increases in size (splenomegaly) in many acute and chronic infections. It takes part in the production of antibodies, as is shown by the fact that some of these diminish after splenectomy. In some cases splenectomy transforms a latent or slight infection into a severe and frequently fatal process. A typical case is the infection of white rats by *Bartonella*. The animals show no signs of infection until the spleen is removed, when a severe infectious condition appears, with intense anemia and a high mortality. If the splenectomized infected rat is joined to a normal rat in parabiosis,[1] the disease is controlled; the spleen therefore acts through a humoral mechanism (Flaum and Lauda).

Splenectomy. Removal of the spleen usually produces anemia in man and in several other species. The anemia is not very severe, and recovery frequently occurs after a few months. In the dog the concentration of erythrocytes decreases by 1,000,000 to 3,000,000 per cubic millimeter; anemia is preceded or followed by reticulocytosis and in a few cases by polycythemia. In the course of this anemia the resistance of the erythrocytes to hemolysis by hypotonic salt solution is increased, and sometimes less iron is retained than normally. In the erythrocytes abnormal structures known as "Jolly's corpuscles" are observed not only after splenectomy but also in cases of atrophy of the spleen. A leukocytosis of 20,000 to 40,000 per cubic millimeter, due to an increase in the granulocytes, is generally present for a short time after splenectomy. There is an immediate increase, of short duration, in the thrombocyte count.

There is no satisfactory explanation of these effects of splenectomy. They seem to be due to a regulatory action of the spleen on the bone marrow through the blood.

[1] Parabiosis consists in establishing a permanent connection between the circulation of two animals of the same species. Incisions, opening the peritoneal cavities, are made in the flank of each animal, and the animals are then sewn together. Vascular anastomoses between the animals are rapidly formed, and there is circulatory exchange between them.

CHAPTER 6

The Leukocytes and the Platelets

THE LEUKOCYTES

The white cells or leukocytes are found in the blood and the lymph, and in small numbers in the tissues and tissue fluids. They are divided into granulocytes, lymphocytes, and monocytes. The granulocytes or polymorphonuclear leukocytes are classified according to the staining affinity of their granules into neutrophil,[1] eosinophil, and basophil.

Concentration. There are 5,000 to 10,000 leukocytes per cu. mm. in normal blood. When the concentration is persistently less than 5,000 per cu. mm. it is said that there is leukopenia. When the figure remains constant at 10,000 or more, there is leukocytosis; but it must be noted that 11 per cent of normal persons have a concentration slightly above this maximum. The average figure in basal conditions (fasting, and physically and mentally at rest) is 7,000 per cu. mm. The formation and destruction of leukocytes are carried on continuously, and the concentration of leukocytes in blood is the result of an equilibrium between these processes that is a true homeostatic mechanism.

The concentration of leukocytes is not the same in the large blood vessels as in the capillaries. When the circulation is slowed down, the number of leukocytes in the small vessels increases; the cells go toward the periphery of the blood stream, near the endothelium (margination of the leukocytes). In the state of shock provoked by the injection of peptone or histamine, and in anaphylactic shock, there is an abnormal distribution of the leukocytes; there is leukopenia in the peripheral blood and leukocytosis in the blood in the abdomen.

[1] In some mammals, amphophil (staining with both acid and basic dyes) instead of neutrophil granules are found.

Table 7. Concentration of Leukocytes in the Blood

Leukocytes	*Absolute concentration of leukocytes, number per cu. mm.*		*Relative concentration of leukocytes, %*	
	Range	*Average*	*Range*	*Average*
Granulocytes				
Neutrophil. .	3,000–7,000	4,300	55–65	65
Eosinophil. .	50–500	200	1–4	2
Basophil. . . .	0–50	25	0–1	0.5
Lymphocytes. .	1,000–3,000	2,000	20–30	27.5
Monocytes. . . .	100–600	400	4–10	5
Total.	5,000–10,000	7,000	. . . . .	100

The percentage of the different types of leukocytes is called the relative count.

The increase in concentration of only one type of cell is known, according to the cells involved, as neutrophilia, eosinophilia, basophilia, lymphocytosis, or monocytosis. A decrease in concentration is known as neutropenia, lymphopenia, or monocytopenia. The variations in the concentration of the different leukocytes cannot be appreciated by examining only the relative count or percentage of cells; only the absolute count can give an accurate picture. Thus in a case of leukocytosis with 15,000 leukocytes per cu. mm., where the percentage of lymphocytes is only 15, there is no lymphopenia, because the total number of these cells per cu. mm. is 2,250, which is a normal figure.

In newborn infants a high count of 20,000 or more leukocytes per cu. mm. is usually ob-

served, but the concentration rapidly falls to a normal figure. In children lymphocytes are more numerous (50 per cent) than in adults; they diminish gradually so that the adult figures are reached by puberty (Fig. 15). In pregnancy there is slight neutrophil leukocytosis. Violent exercise, emotion, pain, and the injection of adrenaline provoke a rapid increase in the leukocyte count, due mainly to the evacuation of leukocytes from the blood stores. In the course of a single day considerable fluctuations in the white cell count have been found in the same subject; in some cases variations of 2,000 per cu. mm. in 1 hr. have been observed. The so-called digestive leukocytosis seen after the midday meal has been recently considered not as caused by the ingestion of food but simply as a slight rhythmic increase (of about 2,000 per cu. mm.) occurring in the afternoon, while in the morning lower figures are usually found.

FIG. 15. Neutrophil and lymphocyte count at different ages. Shaded areas correspond to the range of variation in normal adults.

Neutrophilia, causing a leukocytosis of 20,000 to 40,000 and more, is frequently observed. It is found (*a*) in infection by bacteria, especially by cocci, fungi, viruses, and parasites; (*b*) in cases where there is suppuration, such as abscesses or appendicitis; (*c*) in many intoxications; (*d*) after injection of foreign proteins; (*e*) transitorily after hemorrhage.

Eosinophilia is observed in (*a*) infestation by parasites, such as trichinosis, hydatidosis, hookworms, etc.; (*b*) allergic states, such as asthma; (*c*) certain cutaneous diseases, etc.

Leukopenia is observed in (*a*) anaphylactic shock and shock induced by the injection of peptone, both conditions in which the leukocytes are accumulated in the small vessels of the abdomen;[1] (*b*) certain infectious conditions produced by bacteria (typhoid, sepsis, and tuberculosis), viruses (influenza), and protozoa (malaria); (*c*) cases in which hemopoiesis decreases (aplasia of the bone marrow, etc.); (*d*) certain intoxications (benzene, pyramidon, sulfonamides, thiouracil, etc.); (*e*) exposure to radioactivity. In some cases the leukocytes diminish considerably, the white cell count remains consistently below 2,000 or even less, and there is severe infection of the throat; many of these cases end fatally. This condition is known as agranulocytosis. Injections of pentose nucleotide have been used to stimulate granulopoiesis and of penicillin to prevent or cure serious infections that may occur in these cases. Eosinopenia has been observed after the injection of the adrenocorticotrophic hormone of the hypophysis in subjects with intact adrenals, the maximum decrease occurring 4 hr. after the injection. In patients in whom the adrenal glands have been damaged (Addison's disease) this response was not observed; therefore it is due to an increase in the corticoadrenal secretion. Cortisone, one of the steroids of the adrenal cortex, also provokes eosinopenia.[2]

Lymphocytosis occurs in a few acute infectious diseases (*e.g.*, whooping cough); it is more common in chronic infections (*e.g.*, syphilis). In the acute stages of tuberculosis there is lymphopenia, the decrease in leukocytes being greater in the more severe forms; when the patient improves, lymphocytes increase up to the normal figure or a little above. Lymphopenia is also one of the signs of Selye's "alarm reaction" to trauma or sudden stress. The adrenocorticotrophic hormone of the hypophysis seems to play a part in regulating the concentration of lymphocytes in the blood. When the secretion of this hormone increases, it provokes hypersecretion of the corticoadrenal hormones, which produces atrophy of the lymphoid tissues and destruction of some of the cells; there is a marked decrease in the circulating lymphocytes and eosinophils.

Lymphopenia seems to increase the severity

[1] After a few hours leukopenia is followed by leukocytosis.

[2] FORSHAM, P. H., *et al.*, *J. Clin. Endocrinol.*, 8, 15, 1948.

of infections and favor the development of experimental cancer (Murphy). These facts suggest that the lymphocytes play an important part in immunity.

The origin of the leukocytes. The granulocytes are formed in the bone marrow; they are therefore of myeloid origin (Table 5). A primitive cell, the myeloblast, develops to a promyelocyte, which gives rise to the myelocytes, cells with a rounded nucleus and specifically staining granules. The nucleus indents, takes the shape of a crook (metamyelocyte), and then becomes lobed (granulocyte). The lymphocytes are formed in the germinal centers of the lymph nodes and other lymphoid tissues. The monocytes have their origin in the histiocytes of the reticuloendothelial system, principally in the liver, and to a lesser degree in other hemopoietic organs.

Neutrophil leukopoietic activity can be estimated by examining the aspect of the nuclei of the neutrophil granulocytes in the blood and establishing the percentage of each type. Arneth's classification (1904), or more usually Schilling's simpler one, is used. Young, recently formed granulocytes have an indented nucleus; as they grow older, lobulations appear and increase in number. There is said to be a shift to the left when young forms with nuclei in the shapes of a U, V, or L predominate, and a shift to the right when the older cells with lobulated nuclei are more numerous (Table 9).

Rat	6.8	13	48	61	20	33	6.3	9	20	2	0.5	73	5

Er = erythrocytes, millions per cu. mm.
Hb = hemoglobin, gm. per 100 cc. of blood.
PCV = volume of packed cells, cc. per 100 cc. of blood.
MCV = mean corpuscular volume, cu. μ.
MCHb = mean corpuscular hemoglobin, μg.
MCHbC = mean corpuscular hemoglobin concentration, gm. of hemoglobin in 100 cc. of erythrocytes.
MED = mean erythrocyte diameter, μ.
L = leukocytes, thousands per cu. mm.
N = neutrophil granulocytes, per cent.
E = eosinophil granulocytes, per cent.
B = basophil granulocytes, per cent.
Ly = lymphocytes, per cent.
M = monocytes, per cent.

Motility. The granulocytes have ameboid movements; they advance by sending out pseudopodia. The other leukocytes are less motile. Nevertheless crawling movements have been described in the lymphocytes, and the

‡ Two, three, four, or five well-marked lobulations.

monocytes sometimes show an undulatory movement of their contour (Carrel).

Tactisms. Certain substances attract (positive chemiotaxis) and others repel (negative chemiotaxis) the leukocytes, as can be demonstrated by placing under the skin small capillary tubes containing the substances. Several hours after broth has been injected into the peritoneum or the pleura, fluid with abundant leukocytes can be removed by puncturing the cavity.

Diapedesis. Microscopic examination of living tissues extended on a warm plate (37°C.) shows the leukocytes migrating from the blood vessels after previous margination; they pass out from the capillaries through the interstices between the endothelial cells. This is known as diapedesis.

Enzymes. Neutrophil granulocytes contain several enzymes. There is a protease which acts in an alkaline or neutral medium; it is inhibited by an antienzyme in the plasma. When large quantities of granulocytes are accumulated and disintegrated, the enzyme thus set free digests the tissues (abscesses). Oxidases are found in myeloid cells; at one time they were considered specific for this type of cell, but they have also been found in other nonmyeloid white cells. Lipases, acting on butterfat and on waxes, are found in the lymphocytes. Leukocytes also contain enzymes that digest bacteria (lysozymes). Carrel has given the name of trephones to certain substances (amino acids and peptones) in the leukocytes that stimulate the growth of tissue cultures.

Phagocytosis. Metschnikoff (1883) discovered this important function of the leukocytes, which consists in the ingestion of cells and particles into the protoplasm. The granulocytes, especially the neutrophils, are microphagocytes, *i.e.*, they ingest bacteria and small particles. The monocytes and the histiocytes in the tissues are macrophagocytes, *i.e.*, they ingest larger particles, such as worn-out erythrocytes and cells. These macrophagocytes are mesenchymatic cells, which retain the embryonic capacity of development and have in common the property of phagocytosis. The phagocytes fixed in the tissues form the reticuloendothelial system (Table 10); the term "endothelial" is not quite accurate as these cells are not endothelial cells but mesenchymatic phagocytes.

Table 10. Reticuloendothelial System

Reticuloendothelial cells, or histiocytes

- Fixed histiocytes
  - Connective tissue → Fixed histiocytes
  - Reticulum → Reticulum of the spleen, lymph nodes, bone marrow
  - Endothelium → Sinusoids in liver (Kupffer cells), spleen, bone marrow
  - Microglia
- Circulating histiocytes
  - Tissues → Migrating histiocytes
  - Blood → Monocytes

Phagocytosis is carried out in several steps: (*a*) contact between the particle and the phagocyte; (*b*) ingestion of the particle; (*c*) digestion, if the substance is a digestible protein (*e.g.*, bacteria); if the substance resists the action of the phagocyte, the latter serves as a carrier for the former, or else disintegrates. Several conditions are necessary for phagocytosis to take place: (*a*) contact with the particle must be established; (*b*) there must be an adequate temperature (38°C.), oxygen pressure, and ionic equilibrium (Ca^{++} is necessary). Many factors modify phagocytosis: (*a*) most anesthetics inhibit it; (*b*) thyroid hormone stimulates it, and it diminishes in thyroid insufficiency (thyroidectomy or hypophysectomy); (*c*) it is partially or totally inhibited by certain bacterial products called "aggressins"; (*d*) it diminishes when there is a deficiency of certain vitamins, ascorbic acid, thiamine, or pyridoxin.

Blood serum contains substances which, by acting on bacteria, favor phagocytosis (Denys, 1895); they were called "opsonins" by Wright (1903). Immunized animals have specific antibodies, called "bacteriotropins," which specifically favor phagocytic activity against the bacteria to which the animal has been immunized; these antibodies resist heating and need the presence of the complement (see Chap. 9).

Significance of phagocytosis. The particles and substances taken up by the phagocytes are submitted to a process of intracellular digestion, carried out by means of the enzymes in the cell. Indigestible particles (charcoal) and certain highly virulent bacteria resist this process. Some of the invertebrates normally digest food by phagocytosis; the cells of their digestive tract capture alimentary particles and digest them. Phagocytosis also takes part in the reabsorption of embryonic tissues; *e.g.*, the tail of tadpoles. Finally, phagocytosis plays a fundamental part in immunity—the capture and digestion of germs, a function carried out mainly by the neutrophils (microphagocytes) and histiocytes (macrophagocytes).

Menkin[1] describes several factors of importance in inflammation: (*a*) leukotaxine, a crystalline substance, probably a polypeptide, which increases capillary permeability and the outward migration of leukocytes; (*b*) a factor that stimulates leukocytosis (LPF), a pseudoglobulin (α_2 globulin) destroyed by heat, produced in inflamed tissues, which stimulates the production of granulocytes in the bone marrow; (*c*) necrosin, a toxic euglobulin, which destroys the cells of inflamed tissues, and causes lesions in the liver and kidney if it passes into the circulation; (*d*) pyrexin, a substance which produces fever.

THE PLATELETS OR THROMBOCYTES

These constituents of the blood were described by Bizzozero (1880), who called them "platelets"; they are also known as "thrombocytes." Other names for them are no longer in use ("Hayem's hematoblasts," "globulins," etc.). They exist in the circulating blood and are not artificially formed *in vitro*, as was at one time believed.

Properties of the platelets. They are extremely fragile and have a tendency to stick on any surface (slides, etc.) and to agglutinate together; they are easily deformed and destroyed. Anticoagulants (sodium citrate, heparin) added to the blood help to delay the destruction of the platelets *in vitro*. When kept in good condition they are oval or spindle-shaped, without a nucleus, and from 2 to 4 μ in diameter. They have a low specific gravity and float in the plasma on sedimentation of the erythrocytes, but they can be separated by prolonged centrifugation. The dried platelets have 60 per cent protein and 15 per cent fat; in the ash there is P, Fe, K, S, and Ca. They reduce methylene blue to the leukobase, and they have a measurable oxygen consumption, but their metabolism is not well known. Apparently they have a life span of only a few days.

Origin and destruction. The platelets are formed by the megakaryocytes of the bone marrow. The spleen plays a part in the destruction and possibly in the liberation of these cells (see "Functions of the spleen," Chap. 5).

Concentration. There are about 250,000 (150,000 to 400,000) platelets per cu. mm.; by some methods of counting, from 600,000 to 900,000 are found, but these high figures are probably due to artificial fragmentation. Thrombopenia, or decrease in the platelet count, occurs in (*a*) acute infections; (*b*) peptone and anaphylactic shock, in which there is at first a fall in their number (destruction or redistribution) but soon afterward they reappear; (*c*) certain hemorrhagic diseases, *e.g.*, thrombocytopenic purpuras; (*d*) aplastic anemia; (*e*) relapse of pernicious anemia.

Functions. Platelets easily adhere to particles (India ink, bacteria) floating in the plasma, both *in vitro* and in the circulating blood, a process that seems to favor phagocytosis. Platelets are an important factor in blood clotting: (*a*) they form the knots in the fibrin reticulum; (*b*) they release substances that activate the cofactor for thromboplastin and convert thromboplastinogen into thromboplastin (see Chap. 8); (*c*) on adding platelets to blood, the clot retracts markedly, and it fails to retract when antiplatelet serum is given (Le Sourd and Pagniez); (*d*) there is thrombopenia in several, but not in all (Roskam), of the hemorrhagic diseases with a disturbance in blood coagulation (see Chap. 8, Coagulation of the Blood), *e.g.*, in thrombocytopenic purpura.

When a tissue is wounded the platelets agglutinate and tend to obstruct the small damaged blood vessels. They set free thromboplastin, a blood-clotting factor, and vasoconstrictor substances, which act on the smooth-muscle fibers.

Splenectomy is followed by a transitory increase in the platelet count in healthy animals. In cases of thrombocytopenic purpura there is a

[1] MENKIN, V., *Arch. Path.*, **41**, 376, 1946.

sustained increase in the platelet count after splenectomy, and the hemorrhagic symptoms improve; the clot also becomes firmer.[1]

Hyperplasia of megakaryocytes in the bone marrow has been observed in cases of thrombocytopenic purpura. This has been attributed to (*a*) a compensatory reaction to excess phagocytosis of thrombocytes by the spleen; (*b*) inhibition of maturation and release of thrombocytes owing to an increase in the inhibitory functions of the spleen, *i.e.*, hypersplenia (Dameshek and Miller, see "Functions of the spleen" in Chap. 5).

CHAPTER 7

Hemorrhage and Transfusion. Blood Groups

HEMORRHAGE

Hemorrhage is the escape of blood from the blood vessels. The blood is lost either outside the body (external hemorrhage), or into the tissues and body cavities (internal hemorrhage). The hemorrhage can be arterial, venous, or capillary, according to the nature of the damaged vessel; it can be produced suddenly or slowly and can be moderate or severe according to the amount of blood lost. It can be due to natural causes or can be artificially produced. Hemorrhage due to natural causes can be divided into (*a*) traumatic (road, industrial, and other accidents, war, etc.); (*b*) medical (gastric and duodenal ulcers, pulmonary tuberculosis, etc.); (*c*) surgical (operations, etc.); (*d*) obstetric (childbirth, miscarriage, etc.). Hemorrhage is provoked (*a*) for experimental purposes; (*b*) to obtain blood for transfusion; (*c*) for therapeutic purposes.

Amount of blood that can be lost. Experimental observations on laboratory animals are more numerous than accurate observations in man, but recently these also have been made in volunteers. Sudden hemorrhage should be distinguished from slow or repeated hemorrhage; the former is more severe than the latter. Small hemorrhages can be repeated many times, so that in the course of months or years great quantities of blood are lost; in the intervals between the bleedings, the blood is regenerated. A sudden loss of blood equivalent to 1 per cent of the body weight is well tolerated by animals of many species. A loss equivalent to 3 per cent of the body weight causes death in a large percentage of rabbits and a small percentage of dogs. The majority of dogs die when they lose 55 per cent of the blood volume (Richet). In man, loss of 30 to 40 per cent of the total blood volume endangers life and should be treated without delay by blood transfusion.

Signs and symptoms of hemorrhage. Signs and symptoms of hemorrhage appear and increase in severity as the amount of blood lost increases. At first there is only a slight fall in blood pressure and a more rapid pulse if the patient is standing; if he is lying down there may be no signs or symptoms. A greater loss of blood will cause disturbances even if the patient is lying down. The blood pressure falls, the skin and mucosae are pale, and the hands are cold and moist. Later, generalized sweating may be observed, the pulse slows down, and breathing becomes fast and shallow. The patient is restless and feels cold, especially his hands and feet; there is general malaise and a sensation of weakness and dizziness with nausea, which sometimes leads to vomiting. If a very large amount of blood has been lost, the blood pressure is very low, there is a small, threadlike pulse, and respiration is considerably disturbed (air hunger). The patient responds slowly to stimulation and his eyesight is impaired. In the final stages consciousness is lost, the pupils are dilated, the sphincters relax, convulsions may occur, and the patient dies. Even a small loss of blood may provoke alarming symptoms because of emotional stress: paleness, rapid pulse, disturbed breathing with increased pulmonary ventilation, dizziness, and sometimes fainting. Bloodletting should, therefore, always be performed with the patient lying down, not standing up or even sitting.

Children and old people are more sensitive to

hemorrhage than adults. Cold, trauma, and general weakness diminish the resistance to hemorrhage. Even the loss of a small amount of blood is dangerous in shock or adrenal insufficiency.

If 500 cc. of blood is rapidly extracted from a vein, the systolic blood pressure falls only slightly and there is a 15 to 30 per cent increase in the pulse rate; the cardiac output does not vary. If the amount removed is increased to 1 liter, the blood pressure falls and there is usually a slow pulse when the subject is lying down; if he rises the pulse rate increases, the pressure falls even more, and he may faint. Sometimes fainting is due to emotional stress (fear), but the loss of blood alone may be sufficient cause. The frequency of fainting increases as the amount of blood lost is greater. Thus in a series of subjects who lost about 540 cc. of blood, fainting was observed in 8.5 per cent; in another series in which the blood lost was from 800 to 1,000 cc., 39 per cent fainted, and 52 per cent of a series which lost 1,000 to 1,200 cc.

Rapid hemorrhage in anesthetized animals causes a fall in blood pressure and always increases the pulse rate. In nonanesthetized human subjects these signs are not necessarily present in cases of severe hemorrhage. The blood pressure and cardiac output may remain normal for a time, thanks to compensatory reactions; moreover, bradycardia is more frequently observed than tachycardia. The blood pressure is maintained at a high level as a result of the increase in the peripheral resistance produced by constriction of the arterioles. This vasoconstriction is also the cause of paleness and the sensation of cold. When there is a sudden fall in the peripheral resistance, brought about by dilatation of the arterioles, the blood pressure diminishes and the circulation of the brain is deficient; this causes dizziness or fainting.

Effects of hemorrhage. The decrease in the blood volume diminishes the circulation in the tissues, and the oxygen supply becomes insufficient (anoxia). This lack of oxygen is first felt by the heart and the central nervous system; when anoxia is prolonged, other organs (liver, kidney, etc.) also suffer damage and their functions are disturbed. Prompt replacement of the blood lost by transfusion produces a spectacular recovery, even when the condition of the patient is extremely serious; but if the blood pressure remains low for a certain time a state of irreversible shock is established, in which blood transfusion produces only a transitory improvement (sometimes no improvement at all) and the patient dies.

Analysis of the symptoms. In moderate hemorrhage, the arterial blood pressure is maintained by constriction of the arterioles, governed primarily by the vasomotor center and to a much lesser degree by humoral factors (secretion of adrenaline and renin).

The venous return of blood to the heart, and therefore the cardiac output, are not diminished by small hemorrhage (up to 500 cc.). A greater loss causes a decrease in the venous return; therefore the venous pressure and the pressure in the right auricle fall, and both the stroke volume and the minute output diminish. In consequence, the arterial blood pressure falls.

The increase in pulse rate and respiratory frequency is due to reflexes provoked by arterial hypotension. Bradycardia (slow pulse) seems to be caused by a reflex having its origin in the peripheral blood vessels, which causes the center of the vagus to discharge impulses and thus slow down the pulse rate; it is called the vasovagal reflex.

Compensatory mechanisms. The following reactions occur as soon as blood is lost:

1. The blood clots, sealing the damaged blood vessels and thus stopping the hemorrhage. This effect of the clot is favored by a low blood pressure and local vasoconstriction (see "Hemostasis" in Chap. 8).
2. Vasoconstriction in the cutaneous and splanchnic areas maintains the level of the blood pressure, or restores it if the pressure has fallen. This also redistributes the circulating blood, so that a larger amount goes to the central nervous system, heart, and lungs, and less to the skin and mucosae, which are pale and cold.
3. Blood stores discharge erythrocytes into the circulation. The spleen plays an important part as a blood reservoir in the dog; its importance in man is still under discussion.
4. The heart rate increases in some cases (see above), and if there is a sufficient venous return, the cardiac output is also increased.

In cases where there is considerable loss of blood, tissue fluid is reabsorbed into the circula-

tion and dilutes the blood. Hemodilution is directly proportional to the loss of blood and reaches its maximum 10 to 24 hr. (exceptionally, 90 hr.) after hemorrhage. This reabsorption of tissue fluid is due to the osmotic pressure of the plasma proteins, which become more efficient for the attraction of water and salts from the tissues into the capillaries because of the fall in blood pressure. The erythrocyte concentration does not vary immediately after hemorrhage, but begins to diminish when the tissue fluid is reabsorbed into the circulation and continues to fall as hemodilution progresses. Hemodilution can be estimated and its changes followed by repeated erythrocyte counts, or readings of the hematocrit, or determination of the specific gravity of the blood. This reabsorption of tissue fluid is probably the cause of the intense thirst in patients who have suffered a severe hemorrhage.

In a later stage the plasma-protein concentration diminishes (hypoproteinemia) because of the loss of plasma and the dilution caused by reabsorption of water from the tissues. Hypoproteinemia is accompanied by a decrease in the osmotic pressure of the plasma, and therefore the reabsorption of fluid from the tissues decreases; also it causes alterations in the tissue cells and retards healing of wounds. If hypoproteinemia is marked, it should be compensated by transfusion of blood or plasma. During the first day following hemorrhage, fibrinogen and other proteins are rapidly regenerated, but complete recovery takes several weeks (see "The formation of plasma protein" in Chap. 1).

The red and white blood cells are also replaced. A few hours after hemorrhage there is a transitory increase in the leukocyte count (neutrophil granulocytes) to a concentration above normal. The lost erythrocytes are gradually replaced, and a normal concentration is restored in 2 to 3 weeks in healthy subjects.

The physiologic basis of the treatment of hemorrhage will be considered when discussing transfusion.

TRANSFUSION

Transfusion is the injection of whole blood, or some of the constituents of blood, into the circulation. Therapeutic use of transfusion is one of the great achievements of modern treatment, especially in the prevention and cure of surgical and traumatic shock. Its application before, during, and after operations has made possible many procedures which, owing to their severity or long duration, would overcome the resistance of the patients if they were not supported by the effects of transfusion. It should not be left until the condition of the patient has deteriorated to an advanced degree. Early transfusion has no contraindications—indeed, it can be and is used as a preventive measure when there is danger of shock—whereas if transfusion is delayed it may be completely inefficacious.

Transfusion is performed for many and varied purposes. Its main indications are (*a*) *restitution and maintenance of blood volume*, *e.g.*, in hemorrhage, shock, or burns; before, during, and after surgical operations; (*b*) *restitution of plasma volume and plasma-protein concentration*, either because of loss of circulating plasma, as occurs in burns where there is abundant transudation of plasma, or because of deficient production of proteins, as in nutritional hypoproteinemia, dystrophic disturbances in infants, etc.; (*c*) *restitution or maintenance of electrolyte and acid-base equilibriums;* (*d*) *compensation of a decrease in erythrocytes or hemoglobin*, *e.g.*, anemia, carbon monoxide intoxication, methemoglobinemia, etc., or to stimulate hemopoiesis; (*e*) *provision of factors to correct disturbances in blood coagulation;* (*f*) *provision of immune antibodies* for the prevention or treatment of infectious diseases, *e.g.*, transfusion of plasma from convalescent or immune subjects to patients with an active infection; (*g*) *replacement of hemolizable erythrocytes*, *e.g.*, in hemolytic disease of the newborn.

The decrease in blood volume produced by hemorrhage, shock, burns, and other conditions, causes disturbances which may rapidly become fatal. The main disturbances are

1. Deficiency in circulating fluid, which causes a decrease in the venous return to the heart and therefore in the cardiac output. Consequently, the peripheral circulation is slowed down.
2. Deficiency of nutritive and respiratory substances in the tissues, due to retarded circulation caused by hypovolemia and constriction of the arterioles. The deficiency in oxygen (hypoxia or anoxia) thus caused provokes an increase in capillary permeability, which results in the loss of plasma fluid into the tissues. The blood volume diminishes even more, and the circulation becomes still more retarded.

3. Disturbances in the functional activity of the tissues because of oxygen deficiency. Those provoked in the central nervous system and heart are outstanding, but if the condition is prolonged, nearly all the cells and tissues of the organism are disturbed.

Transfusion is performed by injecting into a vein (*a*) whole blood; (*b*) plasma or serum; (*c*) serum albumin; (*d*) erythrocyte suspensions; (*e*) colloid solutions; or (*f*) crystalloid solutions (salts, glucose, amino acids, protein hydrolysates).

Blood can be transfused into the marrow of the sternum (Tocantins). Intra-arterial transfusion is not used in medical practice, although it has some theoretical advantages and in certain experiments it has proved more efficacious than intravenous transfusion in the control of shock.

In order to have blood or other suitable material available in cases of emergency, in which transfusion should be performed as soon as possible, blood stores are established in hospitals and field ambulances with preserved blood or dried plasma. "Blood banks" have ready all types of blood, adequately classified. The supply is renewed continually, thanks to voluntary donors. Blood is usually kept at 4°C. with citrate and glucose added; for example, 500 cc. of blood is mixed with 75 cc. of a fluid containing trisodium citrate $2H_2O$, 1.6 gm.; citric acid H_2O, 0.56 gm.; glucose, 1.5 gm.; and distilled water, 100 ml. After a few days in cold storage the erythrocytes release potassium and gradually disintegrate. Special treatises on blood transfusion should be consulted for the technique of the correct use of different kinds of blood.

Transfusion of Whole Blood[1]

Transfusion of whole blood has the advantage of restoring all the constituents of the circulating fluid, but it has certain drawbacks. There are difficulties in obtaining, conserving, and transporting blood; moreover, the compatibility of the donor's and the receptor's bloods must first be established. Transfusion of blood plasma is often used, especially in wartime, because although blood plasma is not the exact equivalent of whole blood, it fulfills many of its functions and is easier to keep and transport.

[1] Transfusion of whole blood was first performed by Lower (1665) in dogs. It was applied to man by Denis (1667). After Landsteiner's discovery of the blood groups (1901) and L. Agote's application of citrate to prevent blood clotting (1914), transfusion became common in medical and surgical practice.

Transfused blood remains in the receptor's circulation for some time. In some cases 50 per cent of the transfused erythrocytes have been found 45 days after they were injected. Transfused plasma proteins are utilized for the nutrition of the receptor's tissues.

The technique most commonly used consists in the intravenous injection of blood in which clotting is prevented by adding tribasic sodium citrate in a concentration of 0.3 per cent. It is advisable to filter the blood just before using it, in case small clots have been formed. The donor must be lying down quietly. Blood is then drawn from one of the arm veins in the amount of 400 to 500 cc.; not more than one-tenth of the blood volume, or 0.8 per cent of the body weight, should be drawn. The blood should be injected slowly into the recipient, drop by drop, but if the blood volume must be quickly reestablished, as in severe hemorrhage, when the life of the patient is in danger, up to 50 or even 100 cc./min. may be given. The blood pressure should be measured frequently in order to decrease the rate of transfusion as soon as it rises. A too-rapid transfusion may cause dilatation of the heart and diminish its efficiency, especially if the heart is diseased. Transfused blood may stagnate in the capillaries, without increasing the circulating blood volume, as occurs in advanced shock.

Three types of danger must be avoided:

1. Errors in technique (gaseous embolism, etc.) or excessive speed of injection.
2. The transmission of diseases, such as malaria, syphilis, or other infections. The donor should be carefully examined and should not be suffering from allergy.
3. Incompatibility of the donor's and recipient's bloods. If the donor's erythrocytes are agglutinated by the recipient's plasma, serious and even fatal accidents can occur.

A large number of accidents observed immediately after transfusion are due to impurities in the citrate solution, especially to pyretogenous substances in the water used in making these solutions. Accidents have also been attributed to the quality of the glass of the receptacle in which the blood is collected and stored; it should be neutral glass, scrupulously clean and sterilized.

Blood transfusion is absolutely necessary, and should be performed without delay, in cases of hemorrhage in which the loss of blood is from 4 to 5 per cent of the body weight; it is advisable when the loss is 2 to 3 per cent, and is usually dispensable when only 1 per cent or less is lost.

Transfusion of Plasma, Serum, and Serum Albumin

During the Second World War, blood plasma (United States forces) and serum (British forces) were widely used in transfusion as substitutes for whole blood. Serum should not be administered immediately after it has been prepared, because then it is toxic, but it soon loses its toxicity. In cases of hemophilia, however, fresh serum containing thrombin has been given (see Chap. 8). Plasma has many advantages over whole blood except in cases of anemia, in which it cannot be substituted because of the need of erythrocytes, and in disturbances of blood coagulation, in which whole blood is more efficacious. It can substitute for whole blood in cases of hemorrhage and shock, and it is better than blood in cases of burns when there is hemoconcentration; it is also indicated in hypoproteinemia. Fluid plasma can be kept for a long time at 4°C.; at this temperature microorganisms cannot develop. If it is to be transported, it is even better to freeze it at -10 to -20°C. Dried plasma is prepared by freezing and drying in a vacuum (lyophilization) so that it redissolves easily in water. This preparation not only occupies very little space and has a relatively small weight, but it can be kept indefinitely and rediluted at any desired concentration. Plasma has the advantage over whole blood that no blood grouping is needed; moreover, the plasma of about fifty donors is pooled in order to avoid a high concentration of any particular agglutinin.

Serum albumin. Crystallized human serum albumin is less frequently used, but in some cases it has certain advantages. It is the most soluble and stable of the plasma proteins. It is well tolerated in transfusion, better than serum globulins, which in some cases cause accidents. The viscosity of a 25 per cent solution is not greater than that of blood, yet this solution has a strong osmotic pressure which attracts water from the tissues into the blood vessels; 80 per cent of the osmotic pressure of plasma is due to its serum albumin. It has been used with good results in cases of shock and of edema with transudation into the body cavities, *e.g.*, in cases of cirrhosis of the liver and of nephrosis. Since 1 gm. of serum albumin is the equivalent of 18 to 20 cc. of plasma, 25 gm. of serum albumin dissolved in 100 cc. of isotonic sodium chloride solution is the equivalent of 500 cc. of plasma; this amount is known as one unit. Serum albumin solution has the following drawbacks: (*a*) it has no antibodies; (*b*) owing to its high osmotic pressure, it might attract an excess of fluid into the blood vessels and thus overload the circulation.

Serum albumin of cattle and horses is usually well tolerated; occasionally it provokes a reaction in the organism, and it should not be injected more than once because specific antibodies are formed after the first injection (see Chap. 9).

Transfusion of Other Solutions

Fluids used as blood substitutes in transfusion should fulfill the following conditions: (*a*) they should have no toxicity; (*b*) they should form colloid dispersions with an osmotic pressure sufficient to retain fluid within the blood vessels, thus maintaining the blood volume; (*c*) they should not be deposited in the tissues or provoke functional disturbances; (*d*) they should not agglutinate or hemolyze the erythrocytes; (*e*) they should not alter the osmotic pressure or the ionic or acid-base equilibriums.

Saline solutions. Intravenous injection of saline solution (NaCl, 0.8 to 0.9 per cent; Locke's solution; etc.) can raise the blood pressure in cases of hemorrhage. If the loss of blood is below 2 per cent of the body weight, this treatment may be useful, but if the loss is greater (3 to 5 per cent), if there is a state of shock, or if hypotension has lasted more than 1 hr., whole blood or plasma should be transfused. Saline has only a transitory effect, as the fluid injected passes through the capillaries into the tissues. Subcutaneous or intravenous saline injections are useful in cases of dehydration. It is best to inject them very slowly, drop by drop; an excessively rapid injection can provoke pulmonary edema.

Colloid solutions. The following colloid solutions are used for transfusion: gelatin in concentrations of 5.5 per cent, gum acacia (6 per cent), pectin, methylcellulose, polyvynilpyrrolidone (3.5 per cent), and dextran (6 per cent in saline). Dextran is a polysaccharide of high molecular weight produced from sugar by *Leuconostoc mesenteroides;* it is metabolized in the human body. These substances are called plasma expanders.

Casein hydrolysate has been used for protein feeding in cases in which protein could not be

given by mouth, and also in cases of hypoproteinemia (Elman) (see Chap. 43, Protein Metabolism).

Erythrocyte suspensions. Erythrocytes separated from plasma can be suspended in saline and used for transfusion in cases of anemia or functional disturbances of the red blood cells, as occurs in CO intoxication.

Accidents following Transfusion

Blood transfusion can cause accidents in several ways: (*a*) by an infection carried in the donor's blood; (*b*) by causing gaseous embolism, due to faults in the technique of transfusion; (*c*) by allergic reactions; (*d*) by a too-rapid injection of blood, which can produce dilatation of the right ventricle, acute cardiac insufficiency, and sometimes pulmonary edema; (*e*) by an error in establishing the compatibility of the donor's blood. The last cause is the most frequent; half the deaths following transfusion are due to it.

The effects of transfusion of incompatible blood occur in three stages:

1. Immediately, there is a tingling sensation in the limbs, lumbar pains, precordial oppression, shivering, cyanosis, tachycardia, a fall in blood pressure, and in some cases death. These reactions are due to the obstruction of small blood vessels by the agglutinated erythrocytes.
2. An interval follows during which the clumps of erythrocytes are dissolved, hemoglobin from the hemolyzed erythrocytes diffuses into the plasma, and in some cases jaundice appears.
3. Later there are signs of renal insufficiency, albuminuria, oliguria, and sometimes anuria and death; hemoglobin crystals are found in the renal tubes. In other cases diuresis gradually increases and the patient recovers.

BLOOD GROUPS

Pseudoagglutination and agglutination. When blood in which coagulation is prevented is left standing, the erythrocytes form *rouleaux* and sink to the bottom of the flask; shaking disperses the erythrocytes, which are thus again suspended in the plasma. This formation of *rouleaux* is not real agglutination but pseudoagglutination.

Erythrocytes placed in blood serum taken from a subject of another species are usually agglutinated into clumps that are not dispersed by shaking (heteroagglutination). Erythrocytes placed in blood serum of a subject of the same species can either remain dispersed and gradually settle at the bottom of the receptacle (erythrosedimentation) or become agglutinated (isohemoagglutination, Landsteiner, 1900). In pathologic cases the erythrocytes of an individual can be agglutinated by that individual's own serum (autohemoagglutination).

Blood groups. Any human blood can be classified into one of four groups, according to the presence or absence of two substances in the stroma of the erythrocytes. These substances are known as A and B respectively. They can be found separately or together, or they can both be missing. The absence of both these factors is indicated by the letter O (derived from zero). There are therefore four possible cases: (*a*) the erythrocytes do not have either the A or the B factor (group O); (*b*) the erythrocytes have factor A, but not B (group A); (*c*) the erythrocytes have factor B, but not A (group B); (*d*) the erythrocytes have both A and B (group AB). These substances, which condition isoagglutination, provoke the formation of specific agglutinins when injected into an animal of another species, *e.g.*, a rabbit; the immunologic term for them is "agglutinogens."[1]

Erythrocytes of subjects in the O group are not agglutinated by agglutinins α and β of human sera. Erythrocytes of subjects in group A are agglutinated by the anti-A factor, or α agglutinin. Erythrocytes of subjects in group B are agglutinated by the anti-B factor, or β agglutinin. Erythrocytes of subjects in the AB group are agglutinated by both the α and the β agglutinin. No blood has an agglutinogen in the erythrocytes and the corresponding agglutinin in the plasma.

Landsteiner has established the composition of the blood in the four groups with respect to the agglutinogens in the erythrocytes and the agglutinins in the plasma (Table 11). Thus the α agglutinin (anti-A factor) is found in the plasma of groups O and B, but not in groups A and AB; the β agglutinin (anti-B factor) is found in groups O and A, but not in groups B and AB. Subjects in group O therefore have both the agglutinins in their plasma, and subjects in group AB have neither.

[1] Antigens A and B have been found also in saliva, gastric juice, sperm, certain tissues, etc.

Terminology. The terminology used so far is that proposed by Dungern and Hirzfeld, and adopted by the League of Nations in 1928. The first classifications were those of Jansky and Moss, which used numbers from I to IV; unfortunately, group I in one of these classifications corresponded to group IV in the other. The international classification is simple and logical, as it indicates the agglutinins and agglutinogens in each group.

Table 11. Human Blood Groups

Group	*Erythrocytes*		*Agglutinin in serum*	*International terminology*
	Agglutinogen	*Agglutinated by serum of group*		
O	O	....	α-anti A; β-anti B	$O_{\alpha\beta}$
A	A	O and B	β-anti B	A_{β}
B	B	O and A	α-anti A	B_{α}
AB	A and B	O, A and B	....	AB_o

League of Nations.....	$O_{\alpha\beta}$	A_{β}	B_{α}	AB_o
Jansky (1907).........	I	II	III	IV
Moss (1910)..........	IV	II	III	I

Racial distribution of blood groups. The relative frequency of the blood groups varies in the different human races. It is the same in Western Europe and in the white population of America (Table 12a), but differs in other parts of the world. The proportion of group A diminishes and that of group B increases as one goes from Western Europe toward the East. The maximum frequency of group B is found in the races of the Far East (Hindu, Manchu, and Malay). The Indian tribes of America have a predominance of individuals in group O; in some of them it is nearly 100 per cent. In parts of America where crossbreeding with Indian stock is common, there is a greater proportion of group O than in the rest of the hemisphere.

Table 12a. Percentage Distribution of Blood Groups

Group	*United States*	*Western Europe*	*Buenos Aires**
O	40–45	43	45.6
A	40	40	39.4
B	10–15	13	10.4
AB	5	4	4.6

* Average of 53,584 individuals. The averages for 5,000 individuals in the city of Córdoba were O, 43.2; A, 41.0; B, 12.0; and AB, 3.8.

Inheritance of blood groups. The blood group is inherited following the mendelian laws.[1] Apparently there are three allelomorphs—A, B, and R. Agglutinogens A and B are conditioned by independent and dominant factors, while the absence of agglutinogen (group O) and the factors for agglutinins α and β are recessive.[2] Hereditary transmission of the blood groups is summarized in Table 12b.

Table 12b. Inheritance of Blood Groups

Blood group of parents	*Genetic constitution of parents*		*Blood group to which offspring can belong*	*Blood group to which offspring cannot belong*
O × O	OO	OO	O	A, B, AB
O × A	OO	AA, AO	O, A	B, AB
O × B	OO	BB, BO	O, B	A, AB
O × AB	OO	AB	A, B	O, AB
A × A	AA, AO	AA, AO	O, A	B, AB
A × B	AA, AO	BB, BO	A, A, B, AB	
A × AB	AA, AO	AB	A, B, AB	O
B × B	BB, BO	BB, BO	O, B	A, AB
B × AB	BB, BO	AB	A, B, AB	O
AB × AB	AB	AB	A, B, AB	O

A disputed paternity can sometimes be excluded when the blood groups of the mother, the child, and the putative father are known, but it cannot be definitely affirmed on the evidence of the blood groups. Information obtained by determining to which of the four principal blood groups the parents and offspring belong gives 1 probability in 7 for the exclusion of a mistakenly attributed paternity.

There are two other supplementary factors in the erythrocytes called M and N (see "Subgroups," below). These factors are of importance in blood transfusion only when transfusion is repeated several times, but they are used in cases of disputed paternity; the probability of excluding a wrongfully attributed paternity is thus increased to 1 in 3. More recently several subgroups in group A and an Rh factor have been discovered; using all these tests, wrongfully attributed paternity can be excluded in 45 per cent of the cases.

The blood group is not clearly established in some children until they are over a year old.

Importance of blood grouping in transfusion. When performing a transfusion it is important to bear in mind that the erythrocytes of the donor must not be agglutinated by the

Table 13. Properties of Plasma and Erythrocytes in Each Blood Group

Group	*Plasma or serum*	*Erythrocytes*
O	Agglutinates erythrocytes of groups A, B, and AB	Not agglutinated by serum of any group
A	Agglutinates erythrocytes of groups B and AB	Agglutinated by serum of groups O and B
B	Agglutinates erythrocytes of groups A and AB	Agglutinated by serum of groups O and A
AB	Does not agglutinate erythrocytes of any group	Agglutinated by serum of groups O, A, and B

plasma of the recipient.[1] Blood from a subject belonging to group A_β should not be injected in individuals of groups $O_{\alpha\beta}$ and B_α, as these have α agglutinin in their plasma; it can be injected into individuals of groups A_β and AB_o. Blood of group B should not be injected into individuals of groups $O_{\alpha\beta}$ and A_β, as these have β agglutinin in their plasma; it can be injected into individuals of groups B_α and AB_o. Blood of group $O_{\alpha\beta}$ can be injected into any subject, as whatever the group of the recipient, the erythrocytes will not be agglutinated because they do not carry an agglutinogen; individuals of this group are called "universal donors." Blood of group AB_o can be injected only into individuals of the same group. As these have no agglutinins, they can receive blood from all the groups; they are called "universal recipients."[2]

For all practical purposes, only the agglutinogens in the erythrocytes of the injected blood are of importance. The agglutinins injected are diluted in the recipient's plasma, where there is also an antiagglutinin, so that agglutination of the recipient's erythrocytes does not occur. There are nevertheless some exceptions to this rule: a few individuals have a very high agglutinin concentration, and in certain cases of severe anemia the recipient's erythrocytes can be agglutinated by the donor's agglutinins and cause serious reactions.[1]

[1] Ottenberg's rule.

[2] The terms "universal donor" and "universal recipient" may be dangerous, as sometimes they lead to serious errors. It is best to match the donor's and recipient's bloods before performing a transfusion. Transfusion of blood from a so-called "universal donor" (group O) may be followed by a reaction if its plasma has a high α, β, anti-M, or anti-N agglutinin concentration. Also the donor's blood may have an Rh factor which is absent in the recipient; in this case the recipient will develop antibodies for this factor.

FIG. 16. Agglutination of erythrocytes in the four main blood groups.

Before a transfusion is performed, the donor's and recipient's bloods must be typed. This can be done if active serums from subjects in groups A_β and B_α are kept in stock. A drop of serum A_β and separately another of serum B_α are placed on a slide, and to each drop another of the blood to be tested (preferably citrated to prevent clotting) is added and mixed with the serum. The slides are watched for 20 to 30 min., but

[1] A and B antigens have been prepared (Witebsky) which can be added to blood of group O donors in order to neutralize the α and β agglutinins it contains.

usually agglutination takes place in a shorter time. If clumps are formed only in the drop with serum A_β, the tested blood belongs to group B_α; if they appear in the drop with serum B_α it belongs to group A_β; if agglutination occurs with both serums, the blood is of group AB_o; and if no agglutination occurs with either serum, the blood tested is of group $O_{\alpha\beta}$ (Fig. 16). This method is not infallible, and it is better to match directly the donor's erythrocytes with the recipient's serum.

A cross test between the erythrocytes and serums of the donor and those of the recipient gives reliable information as to the compatibility of the bloods. In a small test tube 0.1 cc. of 0.9 per cent saline solution, 0.1 cc. of a 5 per cent suspension of the donor's erythrocytes, and 0.1 cc. of the recipient's serum are placed. Another test tube receives the recipient's erythrocytes and the donor's serum. Both tubes are left for 20 min. at 37°C. On shaking the tubes the erythrocytes will disperse if agglutination has not taken place but will remain in clumps if it has.

Subgroups. Two subgroups have been found in group A; these are known as A_1 and A_2. A_1 erythrocytes absorb much more α agglutinin than those of the A_2 type. Subgroup A_1 is five to six times more frequent than A_2. There are also subgroups A_1B and A_2B.

Landsteiner and Levine immunized rabbits against human erythrocytes by repeated injections of blood from the same individual. They were thus able to discover two additional factors called M and N. These are found in the erythrocytes of individuals in all the four principal groups, who can have either factor M or N, or M and N together; there are no erythrocytes without one or both of these factors.

Other factors[1] have also been found in the erythrocytes; among these the most important are the Rh and P factors. Taking into account not only the usual groups and subgroups[2] but also the Rh factor, over 2,500 different varieties of blood have been found.

Rh factors. The discovery of the Rh factors made it possible to (*a*) understand and prevent certain accidents caused by the transfusion of blood apparently compatible according to the data given by tests with the A, B, AB, O system;

[1] Schiff and Boyd, 1942.

[2] O, A_1, A_2, A_3 (very rare), B, A_1B, A_2B, A_3B (very rare) M, N_1, N_2, MN_1, P, P_1, P_2, P_1P_2, S, S_1, the different Rh factors, and several others.

(*b*) understand and treat successfully erythroblastosis fetalis (hemolytic disease of the newborn); (*c*) establish more accurately the individuality of the blood, a fact of considerable value in legal medicine and anthropological studies.

Landsteiner and Wiener[1] discovered a factor (which they called the Rh factor) in the erythrocytes of the rhesus monkey, by injecting blood from animals of this species into guinea pigs, thus obtaining a specific immune agglutinin. When human erythrocytes were tested with anti-Rh agglutinin, the Rh factor was found in 85 per cent of the subjects.[2]

Later work showed there were several Rh factors. This was proved by injecting blood into a recipient in order to provoke the formation of the corresponding agglutinin. The anti-Rh standard agglutinin gave 85 per cent of positive cases, and two other agglutinins, anti-Rh_1 and anti-Rh_2, gave 70 and 30 per cent of positive cases respectively. The Rh_1 factor was then found to consist of an Rh and an Rh_0 factor, and Rh_2 of Rh_0 and Rh''. Furthermore, an agglutinin was obtained that gave 80 per cent of positive cases, including all the Rh negatives. This agglutinin was called anti-Hr as these cases appeared to be the reverse of the Rh positive ones.

Fisher and Race[3] observed that a subject could have the Rh' and the Hr factors, or one of these, but could not be lacking in both, a fact that made them suppose these factors were alleles. Rh'' and Rh_0 did not behave as alleles of Rh' or of each other. Fisher and Race therefore stipulated the hypothesis of the existence of three pairs of genes in three loci situated very close to one another in the same chromosome. The Rh' factor was called *C* and its allele Hr, *c*; Rh_0 was called *D* and Rh'', *E*. The existence of alleles *d* and *e* was thus postulated, and these were found later by Mourant[4] in 1945 (factor e) and Haberman *et al.*[5] in 1948 (factor d) which

[1] LANDSTEINER, K., and A. S. WIENER, *Proc. Soc. Exper. Biol. & Med.*, **43**, 223, 1940; **54**, 316, 1943.

[2] This percentage was found in the white races, with the exception of the Basques, of whom only 64 per cent are Rh positive (ETCHEVERRY, M. A., *Ciencia e Investigación*, **3**, 47, 1947). In Negroes, Chinese, and American Indians higher percentages have been found.

[3] RACE, R. R., *Nature*, **153**, 771, 1944.

[5] HABERMAN, S., J. M. HILL, B. W. EVERIST, and J. W. DAVENPORT, *Blood*, **3**, 682, 1948.

confirmed the Fisher-Race hypothesis. Later a C^w antigen was found in locus C and a D^u antigen in locus D. All the facts so far discovered fit into the three-loci theory of Fisher and Race.

At first the Rh positive cases were considered dominant, and the Rh negatives as recessive, but after the anti-c (anti-Hr) agglutinin was obtained it was shown that both alleles had the same single-dose expression (*i.e.*, were equally dominant), as is the case of the A and B factors in the ABO system considered in a previous paragraph. The other alleles D, d, E, e, also show single-dose expression; therefore whenever any of these factors are genetically present they can also be demonstrated in the erythrocytes by means of the corresponding agglutinin.

Twelve different Rh chromosomes have been identified; they are CDe, cde, cDE, cDe, C^wDe, cdE, Cde, CDE, CD^ue, cD^uE, cD^ue, and C^wde. Theoretically these chromosomes can give rise to 78 different genotypes. Race *et al.*[1] found 13 of these possible genotypes in a series of over one thousand subjects tested (Table 14). There were also two examples of D^u but they are included in the ordinary D groups. Injection of human blood with any type of Rh factor into a subject without this factor in his erythrocytes provokes

the appearance of the corresponding anti-Rh agglutinin and hemolysin in about 12 days. A second transfusion of the same Rh blood is followed by agglutination and hemolysis of the injected erythrocytes and by severe reactions in the recipient. In these cases blood typing with the α and β agglutinins is not sufficient to establish the compatibility of the donor's and recipient's blood; by repeated transfusion anti-Rh agglutinin is formed in the recipient's plasma, which agglutinates the transfused erythrocytes. Direct matching of the donor's and recipient's blood before each transfusion is the only sure way of knowing if they are compatible.

Hemolytic disease of the newborn. In this disease, also called erythroblastosis fetalis or severe congenital jaundice, the fetus may die *in utero*, with widespread edema and ascites (fetal dropsy), or may be born alive, but with severe hemolytic anemia and jaundice. There are many erythroblasts in the blood, the liver is enlarged, and in some cases there are lesions in the central nervous system. The pathogenesis of the disease was first demonstrated by Levine and his associates, who showed that hemolysis of the fetal blood is due to isoimmunization of the mother by a factor in the erythrocytes of the fetus which provokes the production of antibodies active on the fetal blood. The condition arises when the factor inherited by the fetus from the father is not present in the mother. An Rh factor is involved in the majority (93 per cent) of the cases, but in the remaining 7 per cent the maternal blood is anti-A, or anti-B, etc. Thus if the father is homozygous for one of the Rh factors and the mother Rh-negative for this factor, the offspring will all be Rh-positive for this factor; if the father is heterozygous the offspring may be either positive or negative for this factor. Not all the offspring of Rh-positive fathers from Rh-negative mothers suffer the disease; the disease is seldom, if ever, seen in primiparas, unless the mother has previously received incompatible Rh blood and been immunized by it. Passage of fetal antigen into the mother's circulation apparently does not occur in the course of pregnancy in sufficient amounts to immunize the mother, but it does occur in the course of labor when the placental maternal blood vessels are open; for this reason the mother's blood with successive deliveries becomes increasingly potent against the incompatible fetal factor.

Treatment consists in bleeding the newborn child as soon as possible after birth[1] and replac-

[1] In order to be prepared for emergencies pregnant women's blood should be typed, not only in respect of the A, B, AB, O system, but also in respect of the Rh system, establishing the anti-Rh potency of the serum.

ing its blood by transfusion of blood negative for the corresponding Rh, or other factor, to which the mother has been immunized. Since these erythrocytes are not destroyed by the maternal antibodies, which attack the fetal red blood cells, they tide over the newborn child until these antibodies have been eliminated.

CHAPTER 8

Coagulation of the Blood

Description. Blood loses its fluidity when it is shed outside the blood vessels; at first its viscosity increases, and then it solidifies into a jelly, so that the vessel which contains it can be inverted without spilling it. A short time after the blood has coagulated, the clot contracts and a yellow fluid (the blood serum) is squeezed out.

It is the plasma that clots. Fibrinogen is found in the plasma in the state of hydrosol; on coagulation it is transformed into a filamented hydrogel called fibrin. Beside blood, other fluids in the organism which contain fibrinogen clot spontaneously when they are shed, *e.g.*, lymph and pathologic exudations. Some other fluids containing fibrinogen, such as normal pericardial and pleural fluid, the liquid in a hydrocele, and pathologic transudations, do not clot spontaneously.

Microscopic observation shows that the clot is formed by a network of fine filaments, which entangles the red and white blood cells in its meshes; the platelets adhere to the filaments once these have been formed. Ultramicroscopic observation shows the formation first of pseudocrystalline needles, which then form threads and the fibrin network. Sometimes blood clotting is incomplete; only clumps of fibrin are formed, but the whole mass of blood does not become solid. If recently shed blood is shaken with glass beads or beaten with a bundle of fine rods while it is clotting, fibrin will be deposited on the beads or rods in the shape of white elastic filaments, to which fibrin owes its name; the remaining fluid, called defibrinated blood, is a suspension of blood cells in serum.

Physiological significance of coagulation. Coagulation of the blood helps to stop hemorrhage, because the clot closes the opening in the blood vessel. When there is a deficiency in blood coagulation, *e.g.*, in hemophilia, a slight accidental wound or a small surgical operation, such as the extraction of a tooth, can cause prolonged bleeding, which lasts for hours or even days and can imperil the patient's life. Normal clotting of shed blood is therefore a defensive mechanism. On the other hand clotting can occur within a blood vessel (thrombosis) and, by obstructing the vessel, cause necrosis in the tissues in which the circulation has been stopped. In other cases an intravascular clot is set free from the place where it has been formed and is carried by the blood stream to a distant part of the body where it obstructs a blood vessel (embolism); this may have serious and sometimes fatal results.

Contraction of the clot and fibrinolysis. Contraction of the clot is similar to syneresis in colloids. Sometimes it takes place rapidly and is marked; at other times it does not occur. Contraction of the clot is conditioned by the concentration of thrombin and thrombocytes. The importance of the latter is shown by the following facts: (*a*) contraction is increased and accelerated by addition of thrombocytes; (*b*) it does not occur in cases of thrombopenia (less than 60,000 thrombocytes per cubic millimeter) or when antithrombocyte serum is added (Le Sourd and Pagniez).

Fibrin is usually slowly dissolved in serum (fibrinolysis). Sometimes fibrinolysis takes place rapidly, *e.g.*, in surgical and traumatic shock, in chloroform intoxication, and in shock produced by the injection of peptone. It is provoked by an enzyme, fibrinolysin (plasmin), which acts as a protease, *i.e.*, a proteolytic enzyme, digesting not only fibrin, but also fibrinogen and prothrombin. In normal plasma, there is profibrinolysin (plasminogen) which is activated by a coenzyme,

fibrinokinase, and is converted into fibrinolysin. Other factors also activate profibrinolysin, *e.g.*, tissue extracts, the streptokinase in streptococci, and substances released by shock (traumatic, peptonic, etc.). An antifibrinolysin has been found, which inhibits fibrinolysin.

Role of the tissues. Blood taken directly from a blood vessel clots less rapidly than blood that has been in contact with the tissues. Damaged cells release substances which accelerate clotting. This phenomenon can be easily demonstrated in birds. Blood which is shed through a wound clots within a few minutes, but if it is drawn directly from an artery and immediately centrifuged, the plasma remains fluid indefinitely. This can also be done with mammalian blood, but it must be drawn into tubes coated with silicone in order to avoid damage to the thrombocytes (which are very fragile) so that by ultracentrifugation they can be eliminated without having been damaged.

THE MECHANISM OF BLOOD COAGULATION

Many theories have been proposed to explain the process of blood coagulation, and a complicated, profuse terminology has been used. This complexity is due to the facts that the knowledge of the mechanism of blood clotting is still incomplete and that most of the substances that play a part have not yet been obtained as pure chemical entities.

There is almost universal agreement as to the transformation of fibrinogen into fibrin by the action of thrombin. The latter does not exist in the circulating blood but is rapidly formed in shed blood by the action on prothrombin of thromboplastin, calcium ion, and an activating or accelerating factor.

The following diagram summarizes this process:

Circulating blood: Thromboplastinogen; Thrombocytes; Thromboplastin cofactor AC globulin (inactive); Ca^{++}; Prothrombinogen → Prothrombin; Fibrinogen; Profibrinolysin

Shed blood — First stage: Thrombotonin (vasoconstriction) ← Thrombocytes; Thrombocytes → Thromboplastinogenase; Thromboplastinogen ← Thromboplastinogenase; Thromboplastinogen → Thromboplastin; Ca^{++}; Thromboplastin cofactor AC globulin (active, labile); Prothrombin; Thromboplastin → (prothrombin complex) → Thrombin

Second stage: Antithrombin (plasma) → Thrombin → Fibrinogen; Thrombin → Metathrombin; Fibrinogen → Fibrin; Profibrinolysin ← Fibrinolysinokinase; Antifibrinolysinokinase → Fibrinolysinokinase; Profibrinolysin → Fibrinolysin; Thrombocytes (contraction of clot) → Fibrin ← Fibrinolysin; Antifibrinolysin → Fibrinolysin; Fibrin → Fibrin-derivates

Heavy line: Quick's prothrombinogenic cycle

FIBRINOGEN

Fibrinogen is the substance that clots and forms fibrin; therefore, only those fluids which contain it can coagulate. It is a globulin with a large molecule; its molecular weight is 500,000, and it has a high viscosity. It is very unstable in the presence of salts. It coagulates when heated to 56 to 60°C. for 10 min. It can be prepared by precipitating citrated plasma with an equal volume of saturated NaCl solution. The precipitate is redissolved by dilution (preferably with citrate) and reprecipitated at least three times, to purify it. Recently it has been obtained by precipitation with ethanol at 0°C. Clotting of fibrinogen is caused by the addition of thrombin, but not by the addition of any one of the substances that give rise to

thrombin, *i.e.*, prothrombin, thromboplastin, or Ca^{++}. Plasma contains only 0.25 gm. per cent of fibrinogen, yet this amount is sufficient to solidify the whole blood, because it forms a network that entangles the cells and absorbs water.

Fibrinogen is formed in the liver (perhaps exclusively). After hepatectomy the concentration of fibrinogen in plasma remains normal or falls slightly; but if blood is repeatedly drawn from a hepatectomized animal, defibrinated, and reinjected until there is no fibrinogen in the plasma, fibrinogen is not regenerated. The small amount of fibrinogen which is replaced apparently comes from stores in the bone marrow and the intestine. If the same procedure is carried out in a normal animal, fibrinogen is regenerated in a few hours.

Thrombin[1]

Thrombin coagulates solutions of pure fibrinogen and oxalated or citrated plasma if there is an adequate electrolyte balance. Thrombin is the cause, not the effect, of coagulation; it is formed from prothrombin by the action of thromboplastin, Ca ion, and a cofactor for thromboplastin even when there is no fibrinogen and therefore fibrin cannot be produced. Thrombin is one of the euglobulins and has carbohydrate groups.[2] When the blood clots, the greater part of the thrombin is found in the serum. Thrombin is adsorbed by fibrin and other surfaces electrically charged (*e.g.*, glass), but not by those that have no charge, *e.g.*, vascular endothelium, surfaces coated with silicone or paraffin, etc. Fresh serum contains a large amount of thrombin, which can be precipitated by alcohol and stored in powdered form; when this powder is dissolved in water, thrombin is set free. There is no thrombin in circulating blood. This fact can be proved by drawing blood into alcohol; the precipitate does not contain thrombin. Because of this lack of thrombin, circulating blood does not clot.

There has been much discussion as to whether thrombin acts as an enzyme or enters into a chemical combination. The following facts have been advanced in favor of an enzymatic activity:

1. At 0°C. thrombin is inactive. Its activity increases with temperature and starts to decline at 50°C. At this temperature it is partially destroyed, and after 5 min. at 60°C. it is completely destroyed.
2. The clotting time is shortened as the concentration of thrombin increases.
3. Thrombin is not used up in the course of coagulation; on the contrary, it increases.

Thrombin is spontaneously inactivated in serum by antithrombin; at 35 to 50°C. inactivation is rapid. An inactive metathrombin is formed, which can be reactivated by adding alkali.

Some snake venoms have thrombins which differ somewhat from those in serum, but which clot fibrinogen solutions, oxalated plasma, and blood.

Calcium Ion

Arthus and Pagés[1] showed that certain anions, such as oxalate and citrate, whose calcium salts have a low solubility, inhibit blood clotting. Restitution of calcium provokes clotting. Calcium acts when in the ionized state (Sabbatani). Furthermore, the addition of salts in high concentration, *e.g.*, NaCl, Na_2SO_4, or even $CaCl_2$, prevents clotting (Schmidt). Coagulation does not take place when the ionic strength of the blood (or plasma) is too high (0.5) or too low (0.01). The concentration of calcium necessary to provoke clotting of decalcified plasma is at a minimum when the ionic strength is 0.03. It must be increased proportionally as the ionic strength is raised. The optimum proportion of Ca^{++} to other ions is 1:16. Other alkaline earths (Mg, Ba) can substitute for calcium, but they act only at higher concentrations; the relative concentrations of Ca^{++}, Mg^{++}, Ba^{++} needed to provoke clotting of decalcified plasma are 1:8:60. Anions inhibit coagulation by a double mechanism: (*a*) by lowering calcium ion concentration (decalcifying effect); (*b*) by raising the total ionic strength. Citrate is more effective than fluoride because of its higher valency (ionic strength); oxalate is approximately as effective as citrate because its lower valency is compensated for by its superior decalcifying effect.[2]

[1] Arthus, M., and C. Pagés, *Arch. de physiol. norm et path.*, **2**, 739, 1890.
[2] Lovelock, J. E., and B. M. Porterfield, *Biochem. J.*, **50**, 415, 1952.

How calcium acts and why it is more effective than other bivalent cations is not well understood. According to Morawitz Ca^{++} has a catalytic effect. It has been suggested that calcium combines with prothrombin and gives an unionized complex,[1] but this theory is not supported by part of the evidence available. It has also been suggested that calcium neutralizes a coagulation inhibitor.[2] The greater effectiveness of calcium may be due to its special solubility in the blood; thus a saturated solution of calcium in plasma ultrafiltrate has twice the calcium ion found in a saturated solution of Ca in distilled water. Calcium ion can neutralize the charge of colloids, *e.g.*, of phosphate colloids. The relative effectiveness of Ca^{++}, Mg^{++}, and Ba^{++} in neutralizing the charge of sphingomyelin is similar to that found in blood clotting; moreover the concentration of the cations must be raised as the total ionic strength increases, in the same way as in coagulation. Calcium plays its part mainly in the first phase of blood clotting, but it also acts in the second phase, *i.e.*, in the conversion of fibrinogen into fibrin by the action of thrombin.[3]

Coagulation is, therefore, dependent on the electrolyte balance of the medium, which conditions the interaction of plasmic colloids, and calcium plays a special part in the maintenance of this balance.

Prothrombin[4]

Prothrombin is a glycoprotein which has been obtained in purified form.[5] There is 15 to 20 mg. of prothrombin per 100 ml. of plasma. It is destroyed by acids, by alkalies, and by heating at 62°C. It is easily adsorbed by tricalcium phosphate, magnesium hydroxide, etc., and can be separated again by elusion in sodium citrate solution. Plasma can be completely deprived of prothrombin by adsorption.

Pure prothrombin does not coagulate fibrinogen. A 25 per cent solution in sodium citrate becomes activated spontaneously (autocatalysis) in 16 hr. (Seegers). In the presence of thromboplastin, cofactor (Quick's labile factor), and calcium ion it is rapidly converted into thrombin. The velocity of this conversion is dependent on these three factors. Certain substances such as gum acacia, gelatine, fine powders, etc., are known as thromboplastic or fibrinoplastic agents because, though not essential to the process, they accelerate it. Activated prothrombin coagulates plasma very rapidly; 1 mg. will clot 2 liters of plasma in 15 sec.

According to several investigators, prothrombin is found in normal circulating plasma in the form of a precursor, called proserozyme (Bordet and Delange) or prothrombinogen (Quick), which is converted into the prothrombin of serum.

Prothrombin is formed in the liver if there is a requisite amount of vitamin K. Prothrombin insufficiency may arise owing to mechanical, thermal, or chemical damage to the liver, or to vitamin K deficiency; also a rare form of congenital prothrombin insufficiency has been described (Quick).

Intoxication by dicumarol inhibits prothrombin formation in the liver.

Vitamin K

Vitamin K (Dam's coagulation vitamin) is necessary for the normal production of prothrombin. When it is not found in the diet or is not synthesized by bacteria in the intestine, prothrombin in the plasma diminishes and spontaneous hemorrhage occurs easily. It is dangerous to submit a patient in this condition to any surgical operation.

Vitamin K was discovered by Dam (1929) in chicks fed a special diet, which provoked a severe condition with ulcers in the gizzard and incoagulability of the blood. These disorders were cured by giving a substance called vitamin K, found in alfalfa, spinach, putrified fish flour, several bacteria, etc. Two chemical substances were isolated which had vitamin K activity (Doisy): vitamin K_1, or 2-methyl-3-phytyl-1,4-naphthoquinone, extracted from alfalfa, and later prepared by synthesis; and vitamin K_2, 2,3-difarsenyl-1,4-naphthoquinone, extracted from putrified fish flour. Several substances prepared by synthesis have the same activity as the natural vitamins K, although their chemical

[2] Overman, R. J., "Blood Clotting and Allied Problems," Josiah Macy, Jr., Foundation, New York, 1949.

[3] Fibrinogen solution purified by electrodialysis is not clotted by thrombin also purified by electrodialysis, but it does clot when a small amount of calcium is added (Rabinovich, R., *Combt. rend. Soc. de biol.*, **95**, 755, 1926).

[4] Prothrombin (Schmidt, Mellanby), serozyme (Bordet), plasmozyme (Spiro), thrombogen (Nolf).

[5] Seegers, W. H., *et al.*, *Arch. Biochem.*, **6**, 85, 1945; *Am. J. Physiol.*, **148**, 563, 1947; **150**, 58, 1947; Robbins, *op. cit.*, p. 75.

structure is simpler. The most active of these is 2-methyl-1,4-naphthoquinone (menadione); it has two to four times the potency of the natural vitamin K.

The maintenance of a normal concentration of prothrombin in blood plasma requires the absorption of a certain amount of vitamin K. This vitamin is not only found in the diet but also synthesized by the bacteria in the intestine. Bile is necessary for the absorption of vitamin K. There is a tendency to spontaneous hemorrhage when the prothrombin in plasma falls below 20 per cent of the normal concentration, and in some cases with an even less marked decrease. Prothrombin diminishes in the following conditions: (*a*) when there is no vitamin K in the diet; (*b*) when vitamin K is badly absorbed because there is no bile in the intestine (obstruction of the common bile duct, biliary fistula); (*c*) in intestinal diseases which disturb absorption (sprue, ulcerative colitis); (*d*) in severe hepatic lesions (hepatosis, intoxications which damage the liver); (*e*) in certain intoxications, such as those following administration of dicumarol, and sometimes of salicylate or sulfaguanidine. Natural or synthetic vitamin K given by mouth, especially when bile is also given so as to facilitate its absorption, improves blood clotting in all these conditions except (*d*) and (*e*).

In the newborn child there is a low concentration of prothrombin in the plasma, which can be the cause of severe hemorrhage. It is therefore advisable to give vitamin K to the mother before delivery, or to the child if there are signs of retarded blood coagulation.

In some animals intestinal synthesis by bacteria is an important source of vitamin K.

Thromboplastin[1]

Thromboplastin rapidly converts prothrombin into thrombin in the presence of calcium ion. This process is considerably accelerated by an activating cofactor (Quick's labile factor). Thromboplastin alone does not clot solutions of pure fibrinogen, or oxalated plasma.

Thromboplastin is found in plasma, especially after disintegration of the thrombocytes. It is also found in human milk and in tissue extracts, especially those of brain, lung, thymus, and placenta. Aqueous extracts are thermolabile, and alcoholic extract with the tissues clots more rapidly than blood drawn directly from a blood vessel; this has been attributed to the effect of tissue thromboplastin. There seem to be two groups of active substances: (*a*) phospholipids related to cephalin; (*b*) lipoproteins not yet well identified.

Quick and others maintain that thromboplastin is originated in a precursor called thromboplastinogen, which is activated by an enzyme in the thrombocytes (thromboplastinogenase); thromboplastin deficiency in cases of thrombocytopenia would therefore be due to a deficiency of this enzyme. According to Ferguson a protease (tryptase) activates thromboplastin and calcium. Inhibitors of thromboplastin have been described (Morawitz, Tocantins). It has been postulated that the passage of placental thromboplastin into the maternal circulation is in part responsible for the condition known as toxemia of pregnancy.

Thromboplastin Accelerator or Cofactor[1]

The conversion of prothrombin into thrombin by thromboplastin and calcium ion is considerably accelerated by a factor in the absence of which the activity of thromboplastin is markedly retarded and diminished. Deficiency of this factor is the cause of retarded clotting and prolonged hemorrhage in certain cases (Owren, Seegers). It is found in very small quantities in normal plasma and is activated by the thrombocytes.

The accelerator factor rapidly diminishes in stored plasma after 1 week, although prothrombin remains unaltered. Hepatic lesions cause both substances to diminish. Dicumarol provokes a lasting decrease in prothrombin, but only a transitory decrease in accelerator factor. Aminophylline and methylxanthines increase thromboplastin cofactor.

According to Seegers prothrombin, thromboplastin, calcium ion, and an accelerator in the thrombocytes form a small amount of thrombin. Thrombin converts inactive AC globulin in plasma into the active AC globulin found in serum. Thrombin would then be formed very rapidly by the interaction of prothrombin,

[1] Thromboplastic or zymoplastic factor (Schmidt), thrombokinase (Morawitz), cytozyme (Bordet, Spiro), thrombozyme (Nolf).

[1] Factor V or convertin (Owren); prothrombin A or labile factor (Quick), accelerator factor (Fantl and Nance), cofactor of thromboplastin (Honorato); accelerator globulin or AC globulin (Ware, Guest, and Seegers).

thromboplastin, calcium ion, active AC globulin of serum, and the accelerator in the thrombocytes.

Owren maintains that thromboplastin with a factor called proconvertin forms convertin, which in the presence of calcium ion converts prothrombin into thrombin. Thrombin thus formed activates proaccelerin (factor V) into accelerin (factor VI) which has a strong accelerator effect on the conversion of prothrombin into thrombin.

The Role of the Thrombocytes

Thrombocytes play an important part in blood clotting. Body fluids that contain fibrinogen but do not clot spontaneously usually coagulate when thrombocytes are added. Any factor which facilitates the adhesion and disintegration of thrombocytes, such as contact, shaking, fine powders, alcohol, or chloroform, causes or accelerates clotting. On the other hand, clotting can be retarded or prevented by drawing blood directly from a blood vessel through a needle coated with silicone into a receptacle also coated with silicone so that the thrombocytes do not adhere to the surfaces with which they come into contact and do not disintegrate. In cases of thrombopenia the blood clots slowly.

Thrombocytes were thought to act on blood clotting by the release of thromboplastin, but it seems that they contain very little thromboplastin. Thrombocytes take part in the formation of thrombin by means of the accelerator factor for thromboplastin (Seegers) and of thromboplastinogenase (Quick) which converts inactive thromboplastinogen into active thromboplastin.

Thrombocytes are an important factor in the retraction of the clot. Also when they accumulate in an opening on the blood-vessel wall they release a vasoconstrictor substance (thrombotonin) which reduces the lumen of the damaged blood vessel, thus contributing to stop the loss of blood.

Theories on the Mechanism of Blood Clotting

As we have seen, a number of factors take part in blood clotting. As yet it has not been possible to experiment with them in their pure chemical form. This limitation has led to difficulties in the interpretation of even well-known facts and has brought forth a great number of theories. These can be divided into physical and chemical theories, although both physical and chemical phenomena play a part in the complex process of coagulation.

Most of the chemical theories are gradually being fused into a common one. There is general acceptance that in shed blood thrombin is formed and acts on fibrinogen, which is transformed into fibrin. This is the fundamental process of coagulation. There are two stages: in the first, thrombin is formed; in the second, thrombin converts fibrinogen into fibrin. Differences in the interpretation of the facts refer to the first phase.

Present theories on the mechanism of blood derive from others submitted some years ago, especially those of Morawitz, and Fuld and Spiro. Bordet, Quick, and others distinguish three instead of two stages in the process of coagulation. In the first stage, thromboplastin and prothrombin are formed from inactive precursors; in the second, the interaction of prothrombin, thromboplastin and its cofactor, and calcium ion forms thrombin; in the third, thrombin converts fibrinogen into fibrin.

There are several physical theories. Some observers maintain that coagulation is due to the union of several colloids in the plasma (Wooldridge, Nolf, Mills) and that thrombin is an effect, not the cause, of coagulation. According to Nolf, thrombozyme (prothrombin) + thrombogen (thromboplastin) + Ca + fibrinogen → fibrin + thrombin. Other physical theories have been advanced (Hekma, Stuber).

ANTICOAGULATING FACTORS

Antithrombin, heparin, and antithromboplastin are factors which inhibit clotting in the organism. In therapeutics heparin and dicumarol or its derivatives are used.

Antithrombin. Old plasma or serum and a few defatted tissues prevent or retard the action of thrombin or fibrinogen. This property has been located in the albumin fraction of serum and plasma. It is attributed to a factor called antithrombin which so far has not been obtained in pure form.

Heparin. Heparin was first extracted from the liver (McLean, 1916) and called heparin by Howell, although it can also be extracted from the lung, the gut, and other tissues. It exerts an immediate anticoagulating effect *in vitro* and *in vivo*, but it must be infused continually or injected repeatedly in order to maintain the blood

incoagulable. There is little or no heparin in normal blood; therefore it is not antithrombin. It does not inhibit the effect of thrombin on fibrinogen unless a factor found in serum albumin (heparin complement) is added. Seegers maintains that thrombin is not destroyed, but that its adsorption by fibrin is increased so that it cannot act on fibrinogen. Heparin has been attributed antiprothrombin activity; also it seems to inhibit or retard the adhesion of thrombocytes on a glass surface (Best *et al.*). It is found in the mast cells of the liver and lung and in the basophil leukocytes of the blood (Wilander). It appears in appreciable quantities in the blood in the course of anaphylactic or peptonic shock and following irradiation in dogs with a hemorrhagic syndrome.

Purified heparin is used in therapeutics to prevent clotting in blood transfusion, to prevent the formation of thrombi after operations or in other situations in which there is danger of thrombosis, in vascular surgery, to prevent the formation of pleural adhesions, etc.

The barium salt of heparin has been crystallized (Charles and Scott). Heparin is mucoitin-polysulfuric acid. Mucoitin is a compound of glycuronic acid and an acetyl derivative of glycosamine. Heparin can be demonstrated in blood and in tissues because it changes the color of toluylene blue to purple. The activity of heparin is measured by comparing its anticoagulating effect with that of an international standard heparin powder, which has 130 units per mg. Heparin can also be estimated by the amount of prothrombin that must be added to neutralize its anticoagulating effect.

Heparin contains 13.8 per cent of S in the form of SO_4. Several anticoagulants have SO_4 in their molecule, and anticoagulating activity is developed in certain substances such as cellulose, starch, and glycogen by incorporating SO_4 into their molecule. One of these, paritol, is used in human therapeutics.

Antithromboplastin. A factor which inhibits thromboplastin has been described by Morawitz, Tocantins, and others. Its chemical constitution and physiological significance are not yet well known.

Dicumarol. A toxic substance, 3,3′-methylene-bis (4 hydroxycoumarin), called dicumarol, has been obtained from fermented sweet clover (*Melitotus* sp.) which provokes hemorrhagic disease in cattle. It has also been prepared by synthesis. It acts on the liver, inhibiting the formation of prothrombin, so that the blood becomes incoagulable. This is not an immediate effect like that of heparin, but takes 1 to 2 days to develop. Prothrombin remains low for a long time, and there is also a transitory decrease in thromboplastin accelerator (AC globulin). Dicumarol activity is measured by determining the prothrombin time, which is prolonged. It has been used in order to prevent postoperative intravascular clotting and to reduce the growth of thrombi, especially in coronary thrombosis.

Hypoprothrombinemia with retarded blood clotting has been reported in cases of intoxication by salicylate or sulfaguanidine (see "Vitamin K" in Chap. 49).

THE FLUIDITY OF THE BLOOD

Circulating blood does not clot because it does not contain thrombin. Moreover prothrombin, thromboplastin, and its accelerator seem to be present as inactive precursors; the thrombocytes are also intact. The stability of the thrombocytes and of the fluid state is dependent on the integrity of the vascular endothelium to which the thrombocytes do not adhere. This is well demonstrated in the following experiment: The jugular vein, filled with blood, is separated from the body between two ligatures. The blood can remain fluid for a long time, but if the endothelium of the vein is damaged or a thread is passed through the vessel, a clot is formed on the damaged surface and all the blood in the vein coagulates. Blood will circulate indefinitely through an anastomosis between two vessels if an intact endothelial surface is carefully maintained. Damage to the endothelium causes local formation of a clot on the wall or within the blood vessel, as is seen in aneurysms and in thrombosis.

There is antithrombin activity in circulating plasma sufficient to neutralize very small quantities of thrombin; injection of a large dose of thrombin provokes massive coagulation of all the blood. An antithrombokinase (antithromboplastin) activity has been described (Morawitz, Tocantins), but its significance is doubtful. The presence of a stabilizing colloid has been postulated (Pickering), but there is no final proof of its existence. Some snake venoms provoke slow intravascular clotting, without the formation of large clots. Fibrinogen is thus used up, and the blood becomes incoagulable; it

has become defibrinated blood (Mellanby, Houssay and Sordelli).

Blood shed into the pleural cavity in moderate quantities remains fluid. It has little fibrinogen and has antithrombin activity; possibly clotting takes place very slowly, and the small amount of fibrin formed is dissolved by fibrinolysis. Menstrual blood remains fluid, except when there is an abundant flow. It has no fibrinogen or thrombin. Probably it coagulates but the clot is dissolved, as a fibrinolytic enzyme has been found (Smith). There is a toxic euglobulin (necrosin) in the menstrual flow.

AGENTS THAT MODIFY COAGULATION

Anticoagulants in Vitro

The following agents prevent or retard coagulation of shed blood:

Cold retards but does not prevent clotting. Local application of cold to a wound can nevertheless stop bleeding by provoking vasoconstriction. Irrigation with warm saline can also stop hemorrhage in some cases by provoking contraction of smooth muscles, *e.g.*, in the uterus.

Prevention of contact. When the blood comes into contact with a foreign surface, thromboplastin and prothrombin are formed from their precursors and thromboplastin accelerator is activated. This contact can be avoided by coating the cannulas and vessels into which the blood is drawn with paraffin or another substance such as silicone that prevents the blood from "wetting" the surfaces with which it comes into contact. Lusteroid tubes also serve this purpose.

Decalcifying agents. Any substance that combines with Ca, so that it is no longer a free ion, prevents blood coagulation. Sodium or potassium oxalate (0.1 per cent), sodium citrate (0.2 to 0.3 per cent), sodium fluoride (0.3 to 0.5 per cent)[1] are commonly used in the laboratory as anticoagulants; sodium citrate, because of its innocuity, is used in medical practice to maintain the fluidity of the blood for transfusion. More recently, ethylene diamine tetra acetic acid is used as an agent capable of chelating calcium ions and maintaining blood fluidity and integrity of platelets.

Concentrated salts. Blood collected into a concentrated salt solution does not clot. The following salts have been used for this purpose: $MgSO_4$ (1:4 of a 25 per cent solution); Na_2SO_4 (an equal volume of a half-saturated solution); NaCl (1:2 of a 10 per cent solution). These salts prevent the formation of thrombin. If the blood is centrifuged or left standing for a sufficiently long time, the plasma is freed from platelets and therefore of thromboplastin, so that it does not coagulate when it is diluted.

Antithrombins. The salivary glands of the leech and the digestive tract of other hematophagous animals secrete anticoagulating substances. Hirudin (Haycraft 1884), an extract of leech's head, and novhirudin, a more purified preparation, have antithrombin activity, and at one time they were frequently used in the laboratory. Heparin (1 mg. for 3 to 5 cc. of blood) has now replaced antithrombins of animal origin in both laboratory and medical practice.

Snake venoms. Some of the snake venoms act as anticoagulants by one of two mechanisms: (*a*) a phosphatidase destroys thromboplastin, as in the case of the venom of the hooded cobra, *Naja tripudians;* (*b*) fibrinogen is attacked so that it no longer clots, as with the venom of *Lachesis flavoviridis.*

Other anticoagulants. Several dyes prevent clotting; many of them have sulfon groups in their molecule, *e.g.*, sodium polyanetholsulfonate (Liquoid Roche), Chicago blue 6B, chlorazol fast pink, etc.

Agents That Accelerate Coagulation in Vitro

The following agents accelerate the coagulation of shed blood:

Heat. At 37°C. blood clots faster than at lower temperatures.

Mechanical contact. Gentle shaking accelerates clotting; vigorous shaking retards it, because it breaks the network of fibrin while it is forming. Clotting is also accelerated by increasing surface contact, *e.g.*, by introducing threads or cotton into the blood, or adding certain colloids.

Calcium. A slight increase in the blood calcium ion concentration accelerates clotting; a high concentration of calcium salts retards clotting.

Thromboplastin. The addition of thromboplastin shortens the coagulation time considerably. Thromboplastin is spread on bleeding surfaces to accelerate clotting and thus stop the

[1] The figures given are those for man; for the dog they should be doubled.

hemorrhage. Fresh aqueous extract of brain, alcoholic extracts of platelets or tissues, and the diluted venom of certain snakes (*Vipera russelli*) are used for this purpose.

Thrombins. Thrombin activity is found in (*a*) fresh serum; (*b*) thrombin extracted from clotted blood; (*c*) some snake venoms (*Bothrops*). The antithrombin in normal blood has very little activity against the thrombin of snake venoms.

Changes in Blood Coagulability in Vivo[1]

A decrease in fibrinogen retards the clotting of blood, and when all the fibrinogen is lost, the blood remains permanently fluid. This is observed (*a*) in certain degenerative processes of the liver; (*b*) in rare cases of congenital hypofibrinogenia, in which fibrinogen is formed in subnormal amounts, or of afibrinogenia, in which it is not formed at all; (*c*) in persons bitten by snakes with coagulating venoms, such as that of *Bothrops* (defibrination of the blood).

The injection of several substances into the circulation of an animal can render its blood incoagulable.

These substances can be divided into two classes:

1. Those which modify the coagulability of the blood as they do *in vitro*, without provoking an organic reaction. Among these substances, heparin should be mentioned in the first place because it is commonly used in therapeutics to prevent intravascular clotting, as it is well tolerated by the organism. Hirudin, polyanethol sulfonate (Liquoid Roche), and anticoagulant dyes are less used in laboratory experiments. Cobra venom and decalcifying salts are used only for experimental purposes because of their toxic effects.
2. Those which provoke an organic reaction and thus modify the coagulability of the blood. Among the substances of this class, the following can be mentioned: (*a*) peptone and substances that provoke anaphylactic shock; (*b*) tissue extracts; (*c*) snake venoms; (*d*) dicumarol.

Peptone shock, produced by rapid intravenous injection of peptone, and anaphylactic shock produce a typical triad: (*a*) hypotension; (*b*) leukopenia; (*c*) incoagulability of the blood. Hypotension is due mainly to contraction of the suprahepatic veins, which causes stasis in the portal system and thus diminishes the venous return; there is also some peripheral vasodilatation. Leukopenia is caused by the retention of the leukocytes in the abdominal blood vessels. Incoagulability of the blood is produced by the liberation of heparin from the liver; heparin prevents the blood from clotting even when thrombin is added. In hepatectomized animals, peptone does not provoke incoagulability of the blood.

The injection of tissue extracts or of thrombin produces different effects according to the dose:

1. Large doses provoke massive clotting of the blood.
2. Small doses produce shock, with hypotension and leukopenia. In a first stage blood clotting is accelerated (positive phase); in a later stage it is retarded or prevented (negative phase). This negative phase is due to the antithrombin effect produced by the discharge of heparin from the liver.

Injection of thrombin extracted from clotted blood, or of thrombin-acting snake venoms[1] is followed by a positive and a negative phase. The negative phase is accompanied by a decrease in the concentration of fibrinogen or even the total absence of fibrinogen from the plasma (defibrinated blood).

Dicumarol retards coagulation because it diminishes prothrombin. The effects are evident only after one or two days, and they last from 2 days to 2 weeks, according to the dose.

TECHNIQUES FOR DETERMINING THE COAGULABILITY OF THE BLOOD

Coagulation time. Many different methods have been proposed; in all of them the time in which the blood clots in certain standard conditions is determined, and compared with the normal. The end point is detected in different ways, and considerable experience is required to obtain comparable results. The usual procedure is as follows: Blood is drawn from a vein into Pyrex glass tubes 8 mm. in diameter, previously rinsed with isotonic salt solution; 1 cc. of blood is put into each of three tubes, and these are submerged in a bath at 37°C.; every 30 sec. one or two of the tubes are examined, and by gently inclining them the formation of the clot is observed; the end point is taken when the

[1] Quick, A. J., *Physiol. Rev.*, 24, 297, 1944.

[1] The venoms of *Bothrops alternata* (*yarará* snake) and *B. neuwiedii* also provoke fragility of the blood vessels and hemorrhages in the nose, gums, and intestinal tract.

clot adheres to the walls of the tube. The third tube is left quiet and examined only when the blood in the others has clotted. The average time taken by the three tubes is the coagulation time; normally it varies from 5 to 15 min.

Bleeding time. A small wound is made by pricking the lobe of the ear with a lancet or a needle; the blood that flows is dried by gently touching the wound with filter paper every 30 sec.; when the paper is no longer stained, bleeding has ceased (Duke). Normal subjects have a bleeding time of 1 to 4 min.

Ivy has proposed the following technique for measuring the bleeding time: the cuff of a sphygmomanometer is placed on the arm and the pressure is raised to 40 mm. Hg. On an area of the forearm where there are no veins, the skin is pricked 2 to 3 mm. deep with a spring lancet. At 30-sec. intervals the blood is dried until it ceases to flow. The normal bleeding time is 2 to 6 min.

Prothrombin determination.[1] Quick had proposed a one-stage method for estimating whether there is sufficient prothrombin. Standard active thromboplastin and calcium are added to oxalated plasma; normal plasma clots in 11 to 13 sec. It is now known that retarded clotting observed with this method may be due not only to deficiency in prothrombin but also to insufficiency of accelerator factor or other causes. Two-stage methods are now used more frequently. In the first stage, plasma is defibrinated and thromboplastin and calcium are added; this is added in graded concentrations to a standard solution of fibrinogen and the concentration which clots in 15 sec. is noted. Several modifications have been proposed. Quick adsorbs prothrombin in plasma by means of tricalcium phosphate, and afterward it is separated by elusion in sodium citrate solution. This is added to rabbit plasma free of prothrombin together with thromboplastin and calcium. These methods are used in order to study the mechanism of coagulation in patients on whom operations have to be performed, especially in those suffering from hepatic diseases. They are also useful for following up the effects of dicumarol.

Other determinations. The platelet count and quantitative estimations of fibrinogen and Ca, or of the retraction of the clot, are also made in some cases.

HEMOSTASIS

Hemorrhage is stopped (hemostasis) principally by three mechanisms:

1. Local vasoconstriction, which can last from several minutes to several hours, is of great importance. Blood continues to circulate by collateral vessels that have not been damaged. The contracted vessels can resist considerable internal pressure without opening. When they again dilate, the damaged walls have been stopped up by other means (platelets, clots). Vasoconstriction is responsible for the stopping of hemorrhage in the rare cases of afibrinogenia (absence of fibrinogen) in which the blood does not clot. Vasoconstriction is produced by (*a*) direct response of the muscles in the blood vessels; (*b*) axonic and true reflexes; (*c*) vasoconstrictor substances, especially those released by the thrombocytes (serotonin).
2. Platelets "stick" to a damaged part of the vascular endothelium. If a small blood vessel is pricked with a needle, the opening is stopped up by a white thrombus formed by platelets agglutinated in a mesh of fibrin. Pathologic alterations in the endothelium also attract the platelets and cause intravascular clotting. A decrease in the platelet count is accompanied by soft, loosely adhering clots. This is observed, together with fragility of the capillaries, in the condition known as purpura hemorrhagica.
3. Blood clotting stops hemorrhage by occluding the opening in the damaged vessels. It is of primary importance, as is seen in patients who suffer from incoagulability of the blood. In these cases the slightest trauma causes severe bleeding—either large hematomas (bleeding in the tissues) or, if an open wound has been made, considerable loss of blood. The simplest surgical operations (*e.g.*, extraction of a tooth) can cause severe, and in some cases fatal, hemorrhage.

Blood clotting can be accelerated by local application of substances impregnated with thrombin or thromboplastin, but the latter is

less efficacious than the former. Substances used as a support for thrombin are gauze, fibrin in meshes or membranes, gelatine sponges, oxidized cellulose, etc. Thrombin and thromboplastin should not be injected intravenously, because this procedure may provoke serious accidents.

PATHOLOGIC ALTERATIONS OF BLOOD CLOTTING

Thrombosis. Intravascular clotting is called thrombosis. It is most frequently observed as a complication of phlebitis in the lower limbs after childbirth and surgical operations. Thrombosis is favored by (*a*) lesions in the endothelium of the blood vessels (phlebitis, arteriosclerosis, etc.) or the cardiac valves; (*b*) agglutination of the thrombocytes; (*c*) slow circulation due to several circulatory disturbances—increased viscosity of the blood, immobilization of the limbs, etc.; (*d*) metabolic disturbances (cachexia, obesity); (*e*) infections and allergy; (*f*) excess heat or cold, radiations; (*g*) coagulating agents (metals, snake venoms, etc.). Clots can be released from a thrombus and, passing through the right cavities of the heart, cause pulmonary embolism with more or less serious, and sometimes fatal, results. Heparin and dicumarol have been used with good results in the prevention of thrombosis after operations in which it is likely to occur, and in cases of myocardial infarction in order to prevent extension of coronary thrombosis.

Purpura. Spontaneous hemorrhage in the skin and mucosae is called purpura. It is due in some cases to fragility of the capillary walls. Thrombopenia is observed in some forms of purpura; bleeding time is prolonged, and the clot is soft and does not retract.

Hemophilia. This is a hereditary disease transmitted by females, who do not suffer from it themselves, to some of their male offspring according to the mendelian laws of heredity. Blood drawn from a vein of one of these subjects clots very slowly, sometimes only after several hours. Even small wounds cause severe hemorrhage; this tendency to bleed profusely lasts throughout life. The concentration of fibrinogen, calcium, thrombocytes, thromboplastin accelerator, prothrombin, heparin, and plasma proteins is normal. The blood clots if thrombin is added. Blood does not coagulate in these patients because thrombin is not formed owing to a deficiency in thromboplastic activity.

The following hypotheses have been advanced to explain hemophilia:

1. The platelets are abnormally resistant and do not set free thromboplastinogenase. This hypothesis has not been confirmed.
2. There is a congenital deficiency in thromboplastinogen (Quick).
3. There is an inhibitory factor which prevents the formation of thrombin.
4. Normal plasma contains a substance which shortens the coagulation time of hemophilic blood. This substance is not found in the plasma of subjects with hemophilia. The substance, together with the globulins, can be obtained from normal plasma.

When it is necessary to staunch hemorrhage in hemophiliac patients, the coagulation time can be shortened by (*a*) transfusion of normal blood (Weil, 1905); (*b*) injection of the antihemophilic factor in normal plasma; (*c*) local application of thrombin or thromboplastin.

Hepatic insufficiency. Removal of the liver is followed by a gradual increase in the coagulation time. Fibrinogen, prothrombin, and the thromboplastin accelerator diminish. Similar changes, especially the decrease in prothrombin and thromboplastin accelerator, have been observed in patients suffering from diseases of the liver. The liver continually replaces plasma proteins, fibrinogen, prothrombin, etc., which become deficient if the liver ceases to produce them in normal amounts.

Diseases with disturbances of blood clotting. In many cases there may be abnormal blood clotting, *e.g.*, in diseases which cause hypoproteinemia. Hypofibrinogenia or afibrinogenia, thrombocytopenia, deficiency of thromboplastin cofactor, increase in heparin or antithrombin may be the cause of disturbances in blood clotting.

CHAPTER 9

Immunity

Definition. After death the body is invaded by the microorganisms living in its cavities; the activity of these organisms is the cause of postmortem putrefaction. The living organism, however, resists microorganisms (viruses, bacteria, fungi, and protozoa) which form the flora and fauna of its internal cavities or which invade it from the environment; this resistance is called immunity. The defense mechanisms against the soluble products of the activity of these microorganisms, animal and vegetable toxins, and foreign proteins are similar to those which protect the body from the invasion of microorganisms.[1]

Immunity is, therefore, a mechanism of defense against microorganisms, the soluble products of microorganisms, and foreign proteins. Immunity is also the response of the organism to agents that attack its integrity; it is therefore a special form of irritability. Immunity, moreover, can be considered as a metabolic or a digestive process, as it consists in the disintegration of substances that tend to alter the specific chemical composition of the body.

In a struggle between two living organisms, immunity represents the response of the attacked organism to the aggressor. If microorganisms are the attackers, the following may occur:

1. The microorganisms may succumb and be digested or eliminated without causing disease. These innocuous microorganisms are called saprophytes.
2. The microorganisms may cause disease. They are then called pathogens, and their capacity to harm the organism and resist its defense is known as their virulence.
3. Pathologic microorganisms can live in an organism without producing any apparent disease. Subjects which harbor these microorganisms are called "carriers."

[1] Only a brief summary of the principal facts of immunity will be made in this chapter. More detailed knowledge can be obtained in treatises on immunology.

An infection (invasion by microorganisms) may remain localized or may spread to the whole body (general infection). In many cases a microorganism has a tendency to localize itself in a determined organ or tissue, and by whatever way it enters the organism it goes to the preferred organ. This is known as the organotropism of the microorganism.

Natural and acquired immunity. An organism may be refractory to a given microorganism or toxic protein, in which case it will resist the foreign agent without showing any abnormality. If this characteristic is congenital or hereditary, it is called natural immunity. If it is the consequence of disease or of the accidental or provoked invasion by a microorganism, it is called acquired immunity.

Immunity can be acquired actively and passively. Active immunity is the result of

1. A successfully resisted attack by the same microorganism; *e.g.*, after recovery from typhoid fever there is a certain degree of immunity or increased resistance to the typhoid bacillus.
2. A successfully resisted attack by a closely related microorganism; *e.g.*, Jenner's vaccine or cow-pox provokes a mild disease (vaccine pustule) which immunizes the organism against smallpox.
3. Treatment with a living microorganism, the virulence of which has been reduced by drying (antirabies vaccine), heating (antianthrax vaccine), or chemical agents; *e.g.*, culture in a medium with bile diminishes the virulence of the bacilli of tuberculosis, which can then be used as a vaccine for the prevention of tuberculosis (B.C.G. vaccine).

4. Treatment with dead or dissolved microorganisms, *e.g.*, antityphoid vaccine.
5. Treatment with modified toxins; *e.g.*, vaccination against diphtheria is practiced by injecting anatoxin, a diphtheria toxin modified by formaldehyde.

Passive immunity is acquired by transmission from an animal with active immunity. Thus repeated injections of diphtheria toxin into a horse actively immunize the animal and provoke the formation of antitoxin against diphtheria in the plasma; the serum is called antidiphtheric serum. Injection of this serum into a man increases his resistance against diphtheria (passive immunity) for a short time, *i.e.*, until the antitoxin, which is a foreign substance, is destroyed. Antidiphtheric serum is used in the treatment of diphtheria to neutralize the toxin produced by the bacteria; it has little value in prevention of the disease.

Cellular immunity. Cells have, or can acquire, resistance to microorganisms and their products. Cells play an important part in immunity, either through phagocytosis or by the secretion of defense products. Phagocytic activity is especially developed in the leukocytes and the cells of the reticuloendothelial system; they first capture microorganisms that have invaded the organism and then dissolve them. Phagocytosis is the normal process of digestion in protozoa and myxomycetes; it is also observed in the cells lining the digestive tract of some invertebrates and in the migrating cells of many animals. Metschnikoff (1883) first studied phagocytosis and gave it its name. Phagocytosis plays a part in (*a*) the nutrition of certain invertebrates; (*b*) the reabsorption of embryonic and pathologic tissue or cellular remains; (*c*) immunity; (*d*) inflammation. Phagocytosis is favored by opsonins and bacteriotropins in the plasma, which act on bacteria and facilitate their absorption by the phagocytes.

Microorganisms produce dilatation of the blood capillaries and increase the permeability of capillary endothelium, so that plasmatic fluid passes out from the blood to the tissues, which become swollen (edema). Microorganisms also produce soluble substances which attract leukocytes and migrating histiocytes. This process is called inflammation. It is classically described by its four cardinal signs: "rubor, calor, dolor, and tumor"—signs due to vasodilatation and to the accumulation of fluid and cells. The living and dead leukocytes gathered in the inflamed focus form the pus found in abscesses or in the exudation of inflamed mucosae.

Menkin has reported the appearance of the following factors in inflamed tissues:

1. *Leukotaxin*, a substance that increases capillary permeability and attracts and stimulates migration of leukocytes.
2. *Necrosin*, a highly toxic euglobulin that kills the cells locally and damages the liver and kidneys if it passes into the circulation.
3. *Pyrexin*, a factor that provokes fever when introduced into the circulation.
4. *LPF, or leukocyte-promoting factor*, which arises in inflamed tissues, passes into the circulation, and releases granulocytes from the bone marrow.
5. *The leukopenic factor* which arises locally in the course of acute inflammation.

Some corticoids (desoxycorticosterone) and hormones (hypophyseal somatotrophin) stimulate the proliferative capacity of connective tissue. Other adrenal hormones (cortisone and hydrocortisone) have the opposite effect; they inhibit the building up of barriers of granulomatous tissue against invaders; they depress inflammatory reactions and open the way for the spread of infection (Selye).

HUMORAL IMMUNITY

Antigens and antibodies. Chemical substances produced by microorganisms provoke the appearance in the invaded organism of other substances which neutralize bacterial products. These reacting substances are called antibodies, and antigen is the name given to a foreign substance that provokes the formation of antibodies. Antigens are proteins of another animal or vegetable species.[1] Some proteins have little antigenic activity and seldom provoke the formation of antibodies; *e.g.*, insulin, protamine. Bacteria have several antigens (mosaic of antigens), some of them specific to one microorganism, others common to several species. Many toxic or nontoxic proteins of vegetable (abrine, ricin) and animal (venoms of snakes, spiders, and scorpions, serum proteins, etc.) origin have

[1] The lens of the eye is the only tissue capable of provoking the formation of antibodies in individuals of the same species.

antigenic activity and provoke the formation of antibodies.

Haptenes. Certain substances are "partial antigens"; they can unite with antibodies but do not have the capacity to stimulate the production of antibodies. They are more or less complicated carbohydrates or fats, or relatively simple substances. Combined with a protein, they acquire antigenic properties and provoke the formation of antibodies. Landsteiner has called them "haptenes." The pneumococcus, for example, owes its specific pathogenic properties to certain carbohydrates that do not produce antibodies. If these carbohydrates are joined to an antigenic protein, the new compound is capable of stimulating the formation of antibodies that neutralize the pathogenic effect of the carbohydrate.[1] Antibodies for nonantigenic substances are now prepared by uniting these to antigenic proteins.

Antitoxins. Bacteria excrete soluble toxins (exotoxins); they also have toxins (endotoxins) that remain within the microorganism. Repeated injections of increasing doses of a toxin provoke the formation of an antitoxin (Behring and Kitasato, 1890) which neutralizes specifically the toxin injected. Antitoxin is found in the pseudoglobulins of plasma or serum. These antitoxins are used in the treatment of diphtheria, tetanus, and the bites of snakes, spiders, or scorpions. Concentrated antitoxin is the pseudoglobulin isolated from antitoxic serum, separated from other inactive proteins, so that in a smaller mass there is more active and less inactive substance. Pseudoglobulin can be further purified by partial digestion with pepsin, because the active globulin is more resistant to digestion than the inactive globulin that accompanies it. This process gives very active serums which have little inert substance and which seldom provoke the accidents known as serum sickness. The γ globulin of the plasma or serum contains antibodies against many pathogenic agents. Once it has been isolated it can be concentrated to 20 or 25 times its original concentration. This γ globulin has been used successfully in the prevention of measles. Diphtheria antitoxin is found in the β_2 and γ globulins.

Agglutinins. In the course of certain diseases agglutinins for the microorganism causing the disease appear in the patient's serum. These agglutinins can be demonstrated by placing in a test tube the patient's serum and the bacteria causing the disease. After a short incubation period, the bacteria conglomerate in clumps, which are not dispersed by moderate shaking. The appearance of specific agglutinins in the serum of a patient is used in the diagnosis of infection, *e.g.*, Widal's test for typhoid fever. Agglutinins are produced by injecting bacteria or erythrocytes into an animal (*e.g.*, a rabbit); these antibodies are highly specific, *i.e.*, they agglutinate only the bacteria or the erythrocytes of the type injected, and not others. Nevertheless some of the bacteria have an antigen mosaic in which some of the antigens are common to other species. In this case the immune serum also agglutinates other bacteria which have antigens in common with the species used for immunization, but this agglutinating activity is not so intense as for the specific microorganism.

Precipitins. Repeated injections of a soluble protein provoke the appearance of a precipitating activity against the protein in the injected animal's serum. The immune serum is placed in a test tube, and when the protein is added, if there is precipitin in the serum, it becomes cloudy. These precipitins are highly specific against soluble bacterial protein (Kraus, 1897) and many nontoxic tissue proteins (Bordet, 1898). Precipitation tests are used in legal medicine to identify the nature of stains; thus from a blood stain there can be dissolved a protein that will give a precipitate with antihuman serum only if the stain was of human blood. This test has been used by Nuttall to establish the zoological relationship between different species, *e.g.*, between the domestic guinea pig (*Cavia domestica*) and the wild species (*C. cuis*).

Cytolysins. Repeated injections of animal cells into animals of another species will provoke the development, in the injected animal's plasma or serum, of the capacity to dissolve the injected cells. A typical example is that of hemolysins; *e.g.*, by injecting sheep erythrocytes into a rabbit, the serum of the injected animal acquires the power to dissolve (hemolyze) sheep's eryth-

[1] Many tissue extracts act as heterophil antigens; injected into a rabbit, they provoke the formation of hemolysins for sheep erythrocytes. Sordelli, Wernicke, Pico, Fischer, and Deulofeu (*Rev. Soc. argent. de biol.*, **1**, 186, 1920; **5**, 570, 1924) demonstrated that this antibody was active against lipids, but that lipids did not stimulate the formation of the antibody; the lipids joined to a protein had antigenic activity. This fundamental fact was later studied by Landsteiner, who developed his concept of partial antigens or haptenes.

rocytes. Cytolysins are made up of two components: one, which is specific for the cell and resists heat, is known as the amboceptor; the other, which is not specific and is destroyed by heating at 56°C., is called the complement or alexin. Bacteriolysins are cytolysins obtained by injecting bacteria.

ANAPHYLAXIS

Richet and Portier (1902) first described the phenomenon known as anaphylaxis. A toxic (Richet) or nontoxic protein, *e.g.*, horse serum, is injected into an animal; after an interval of one to three weeks the same protein is again injected with serious, sometimes fatal, results. The condition is called anaphylactic shock because of its suddenness and intensity. This hypersensitiveness is specific for the substance injected, which produces a state opposite to that of immunity or protection; hence the name of anaphylaxis used by Richet.

Anaphylactic shock. Anaphylactic shock has been studied in many species, but mostly in the dog (Richet), the rabbit (Arthus), and the guinea pig (Theobald Smith, 1906). Three steps must be considered: (*a*) the sensitizing dose; (*b*) the latent period, or incubation time; (*c*) the shock dose. The sensitizing substances are antigens, *i.e.*, proteins or substances combined with proteins (anaphylactogenic antigens). Very small doses are sometimes sufficient to produce sensitization.

The incubation time is usually two or three weeks. Hypersensitiveness lasts for several months or even years. If the animal is sensitized, the shock dose (preferably injected intravenously) provokes anaphylactic shock. Sensitization is strictly specific; the shock is provoked only by the substance to which the animal has been sensitized. Specificity is not so strict in the rabbit as in the guinea pig. Anaphylaxis can be used to identify the nature of a protein; thus three different proteins with specific sensitizing capacity have been found in horse serum. The shock dose produces the most intense reaction when injected intravenously, but it also provokes shock, although in decreasing order of intensity, when injected into the brain, peritoneum, or trachea, or subcutaneously.

Anaphylactic shock provokes reactions which vary according to the species but which are always the same whatever the antigen used. They are therefore conditioned by the species, not by the antigen. All the tissues react, but the signs observed are due to the contraction of plain-muscle fibers and to increased permeability of the endothelia. In the guinea pig acute anaphylactic shock causes death by asphyxia. The muscles in the bronchioles are contracted so that air goes into the lung but does not come out; on opening the thorax, the lungs remain distended. In the dog there is a typical triad: hypotension, leukopenia, and incoagulability of the blood. Hypotension is due to contraction of the suprahepatic veins, which causes stasis in the portal system. Leukopenia is due to the accumulation of leukocytes in the small blood vessels of the abdomen; a leukocyte count in peripheral and abdominal blood shows a marked difference, and abdominal vasoconstriction is followed by an increase in leukocytes in peripheral blood. Incoagulability is due to the secretion of heparin by the liver which forms antithrombin in the blood. The liver also releases into the circulation histamine; bradycinin, a slow-acting vasoconstrictor (Rocha e Silva); and fibrinolysin. Anaphylactic shock in the dog is similar to shock provoked by histamine, peptone, and other agents. In the rabbit anaphylactic shock causes hypotension due to constriction of the pulmonary blood vessels.

Passive anaphylaxis. If the serum from a sensitized animal is injected into a normal animal, the latter after a few hours becomes sensitized. An injection of the antigen provokes anaphylactic shock, which may be fatal. This experiment demonstrates the existence of a circulating antibody which can be transmitted to another animal. The latent period is necessary for the passive sensitization of the animal's cells, so they can react to the antigen, which only then will provoke shock.

Cellular anaphylaxis. Cellular sensitization can be demonstrated as follows: a sensitized dog is bled, and normal blood is transfused until the animal's blood has been almost completely replaced; a shock dose of the antigen is then injected and shows the animal is still sensitized (Manwaring). An even clearer demonstration is obtained by taking out the uterus of a sensitized guinea pig, washing it free from blood, and submerging it in Tyrode's fluid at 37°C. The tissue survives in good condition and responds to many drugs. When minute quantities of the

antigen to which it has been sensitized are added to the fluid, violent contractions are provoked in the isolated uterus. Other antigens do not produce this effect (Dale).

Desensitization. A very small dose of antigen does not provoke symptoms in a sensitized animal, and protects it from the effects of a larger dose injected a little later, which would otherwise have produced serious and perhaps fatal results. Desensitization can also be obtained by a very slow injection of dilute antigen. In these cases the organism reacts but not with the violent symptoms of shock. Besredka has advocated this method of desensitization in cases in which serum treatment must be given to patients who have been injected with the same serum some time previously.

Theories of anaphylaxis. Many theories have been proposed to explain anaphylaxis, but it is still unknown whether shock is due to flocculation of colloids, or an intense antigen-antibody reaction within the cells, or to the liberation of active substances. Intravenous injection of colloid solutions sometimes provokes shock very similar to anaphylactic shock, without any previous sensitization. During anaphylactic shock, histamine is liberated in the lung of the guinea pig and the liver of the dog. Histamine injection produces the same symptoms as anaphylaxis, but there is no definite proof that anaphylactic shock is due to the liberation of histamine.

ALLERGY

Allergy is an abnormal reaction of the organism to a foreign substance. Its most interesting manifestation is hypersensitiveness. Many people are hypersensitive to animal or vegetable allergens which when given by mouth, inhalation, or injection are capable of producing reactions. Typical among allergic phenomena are vasodilatation in restricted areas of the mucosae, increased capillary permeability with local edema or hemorrhage and contraction of plain muscles, producing hay fever, asthma, gastrointestinal disturbances, conjunctivitis, etc. Serum from these patients injected into other subjects or animals does not passively sensitize them to the allergen, and they do not react to it with the typical allergic syndrome.[1] Local sensitization can nevertheless be produced passively by intradermal injection into a normal subject of a small amount of serum (0.1 cc.) from a sensitized subject. Injection of the allergen into the sensitized area provokes an intense local reaction (itching, redness, swelling, edema); a neighboring area of normal skin does not react to the allergen in this way. This passive transmission of hypersensitiveness to a local area (Prausnitz-Küstner reaction) is due to the existence in the serum of special antibodies (reagins) which have a tendency to remain fixed where they have been injected. Allergic idiosyncrasy is frequently observed. Actual hypersensitiveness is not inherited, but there is a hereditary tendency to acquire hypersensitiveness and to react by an allergic syndrome.

Allergic reactions, in some cases, are more or less inhibited by antihistamine drugs, cortisone, and adrenocorticotrophin.

Bacterial allergy. Bacteria and other parasites provoke hypersensitiveness in the host to some of their constituent substances or excretions. Thus subjects infected with the tubercle bacillus react in a peculiar way if tuberculin is placed on the scarified skin (von Pirquet's reaction) or injected intradermally (Mantoux reaction); there is reddening, swelling, and itching, which does not occur in nonallergic subjects. Patients with a hydatid cyst react in the same way when hydatid fluid is applied to the skin by scarification or intradermal injection (Casoni's reaction).

SECTION TWO

The Circulation

CHAPTER 10

The Circulation of the Blood

THE PROCESS OF cellular nutrition demands a continuous supply of nutritive substances and the subsequent removal of resulting waste products. In unicellular organisms and the simpler multicellular ones, this continuous exchange takes place directly between the cells and the environment. The currents due to differences in temperature levels or other causes, or the simple diffusion of substances in the fluid mass, or the displacement and movements of the organism if they can take place, are enough to ensure the renewal of the environment in the immediate neighborhood of the organism, and therefore the arrival of food and the removal of waste products.

The development of more complex organisms has been made possible by the simultaneous development of a vascular system that serves to carry to all the tissues a fluid, *i.e.*, the blood, the constant circulation of which assures to all the cells the transportation of material necessary for their activity. In vertebrates—the animals in which we are here most directly interested—the vascular system is made up of completely closed tubes, which in no place permit their contents, the blood, to come in direct contact with the cells. The system of tubes within which the blood circulates has different types of structures in its various sections. Three main types can be distinguished: arteries, capillaries, and veins. An important part of the vascular system is the mechanism of propulsion that moves the blood and keeps it circulating, in order that it may arrive at all the tissues in adequate amounts and at an appropriate pressure. The heart is the most outstanding feature of this propulsive mechanism, and for this reason it is considered the central organ of the circulation.

The vascular system, therefore, consists of a series of closed tubes, the arteries, capillaries, and veins, and a central organ of propulsion, the heart. The blood is driven by the heart into the arteries, from which it passes into the capillaries, then into the veins, which return it to the heart. The blood simply passes through the arteries and veins, and as it runs through these vessels there is no significant change in its composition or in its properties. On the other hand, as the blood passes through the capillaries there is an interchange of substances between the blood and the tissue fluids, and the chemical composition and the physical properties of the blood change considerably.

The circulation is an important factor in functional integration and equalization of the chemical and physical properties of the whole organism.

Arteriovenous anastomoses. In certain parts of the body such as the skin, the erectile organs, the balls of the fingers, etc., some of the arterioles open directly into the veins, without an intermediary capillary. This is a normal, but exceptional, arrangement of the blood vessels. Arteriovenous anastomoses play an important part in regulating the volume of blood which circulates through a given region.[1]

Aortic and Pulmonary Circuits. In mammals and in birds there are two complete circuits which begin and end in the heart. Venous blood arrives at the right auricle, passes into the right ventricle, and from there flows through the pulmonary artery to the lungs, where in the capillaries it undergoes the process of arterialization. This arterial blood flows through the pulmonary veins into the left auricle, passes into

[1] CLARK, E. R., *Physiol. Rev.*, **18**, 229, 1938.

the left ventricle, and is sent through the aorta and its branches to the capillaries in the tissues and organs, whence it flows back through the veins into the right auricle. The pulmonary circuit, or lesser circuit, begins in the right ventricle and ends in the left auricle; the aortic circuit, or greater circuit, begins in the left ventricle and ends in the right auricle. The blood flows continuously and successively through these two circuits.

HISTORICAL REVIEW

The first conclusive demonstration of the nature and the principal mechanisms of the circulation of the blood was given by William Harvey in his classic book, *Exercitatio anatomica de motu cordis et sanguinis in animalibus*, published in 1628 in Frankfurt. Harvey developed his ideas by observations and experiments that were made with a faultless method and followed a remarkably logical plan. It is therefore not surprising that his book can be read after more than three centuries, not only with admiration, but also without having to change any of his main conclusions as a result of later discoveries. Harvey's book is one of the most important contributions to science of all times, although its length is only 72 pages.

Harvey's observations and experiments put an end, although not without difficulty, to the vague and inaccurate empirical ideas of his day. Several isolated facts of importance in respect to the circulation of the blood had been known before Harvey made his contribution. Vesalius (1543) described the course of the veins and the anatomy of the heart. Fabritius described the valves in the veins, but he was not aware of their functional significance. Michael Servet (1551) and later Mateo Realdo Colombo (1555) described the passage of blood from the right ventricle through the lungs into the left auricle and ventricle and had some idea of the process of hematosis.[1]

After Harvey, Malpighi (1661) discovered the capillaries and another important stage was completed. Harvey had stated that the blood passed from the arteries to the veins, but he had not said how this was accomplished. The discovery of the capillaries, made possible by the development of the microscope, filled this gap in the knowledge of the circulatory system.

Further historical data will be given in the appropriate places in the following chapters.

[1] According to recent historical research (Haddad and Khairallah, *Ann. Surg.*, **104**, 1, 1936), in the twelfth century Ibn Naffis, an Arab physician, had stated that the blood went from the right ventricle to the left auricle through the lungs.

GENERAL LAWS OF THE CIRCULATION

The general laws of the circulation of the blood will be stated briefly here; later in the respective chapters they will be considered in detail.

The law of pressure. The pressure exerted by the blood on the walls of the blood vessels is determined by the cardiac output in unit time and by the peripheral resistance to its circulation. It is highest above the section that exercises the greatest resistance, *i.e.*, in the arteries. It drops suddenly at the level of the capillaries and continues to fall gradually along the veins, reaching a minimum in the auricles. This pressure gradient is the reason why the blood passes from the ventricles to the auricles in the general and pulmonary circuits.

The law of velocity. The velocity at which the blood circulates is dependent on the caliber of the vascular bed—not on the diameter of each blood vessel, but on that of all the divisions of the main trunk at a given distance from the heart. The ramification of the vessels is such that the sum of the cross-sectional areas of the branches is greater than the cross-sectional area of the parent vessel. Therefore the vascular bed increases as the distance from the heart is greater, reaching a maximum at the level of the capillaries. On the venous side it is progressively reduced as the distance to the heart diminishes, and it is at a minimum at the openings in the auricles. The vascular bed, in both the general and the pulmonary circuits, could therefore be represented by two truncated cones joined by their bases. One of the cones would represent the arterial side; the other, the venous side; and the area where they join, the capillaries. Once this idea of the vascular bed is clear, and taking into account that the velocity of a current in any stream is inversely proportional to the cross section of its bed, it is easy to understand the following law of velocity in the circulatory system: *the velocity of the blood diminishes in the arteries as the distance from the heart increases, it is at a minimum in the capillaries, and it increases progressively on the venous side as it comes nearer to the heart.* The total cross-sectional area of the veins where they end in the auricles is greater than that of the arteries which emerge from the ventricles; therefore the velocity of the blood flow is greater in the arteries than in the veins.

The law of volume flow. The amount of blood passing through a cross section of the circulatory system in unit time is called the volume flow. The circulation is normally maintained without undue stagnation of blood at one point and insufficient filling at others when the following law of volume flow is fulfilled; the amount of blood passing in a given time through a complete cross section of the circulatory system is the same as that passing through a complete cross section at any other point.

If 5 liters of blood passes through the aorta, then at the same time an equivalent amount will pass through the pulmonary artery and the aggregate of the systemic capillaries, etc. The small changes produced by the active modifications in the caliber of the vessels in a limited section are compensated by adequate reactions in other sections.

CHAPTER 11

The Physiologic Properties of the Heart

The heart is responsible for the force necessary to make the blood circulate. It is a hollow organ with muscular walls and has a system of valves so disposed that when the heart muscle contracts the blood that fills the cardiac cavities is driven forward from the venous to the arterial side.

The fundamental properties of cardiac muscle fibers are of essential importance in the function of the heart.

THE STRUCTURE OF THE HEART

The heart has certain structural features that must be known in order to understand many aspects of its function. The heart walls are made up mainly of muscle fibers of a special type. These are cylindrical, with a central nucleus and there are protoplasmic bridges between neighboring fibers, so that the heart muscle as a whole constitutes a syncytium. Continuity between the auricular and ventricular muscles is established by a special bridge, the bundle of His.

Cardiac muscle fibers have the longitudinal striation common to all muscle fibers and cross striations similar to those of skeletal muscle. This similarity in the histologic aspect of cardiac and skeletal muscle fibers does not extend to their physiologic properties. In its contraction, its response to innervation, and the chemical aspects of its activity, cardiac muscle differs fundamentally from skeletal muscle.

The electron microscope shows that in each myocardial fiber there are 300 to 700 myofibrils; these are the smallest contractile units. Capillaries are seen to enter the myocardial fiber carrying blood to the sarcoplasma, nuclei, and myofibrils. Large numbers of sarcosomes (mitochondria and chondriosomes) are seen scattered among the myofibrils and near the poles of the nuclei, but never within the myofibrils.[1]

THE PROPERTIES OF THE CARDIAC MUSCLE FIBER

Four fundamental properties are usually studied in the cardiac muscle fiber: rhythmicity, conductivity, excitability, and contractility.

Rhythmicity. The cardiac fiber has the power of originating within itself the impulse that makes it contract. This is one of the first properties to appear in the course of development. As soon as the heart is formed in the embryo, before the fibers acquire their typical histologic aspect, it contracts rhythmically, and this rhythmic beat persists even after it has been separated from the organism.

After the development of the heart is complete, not all its parts have the same rhythmicity. If the heart is removed from the body it will continue to beat for some time. The ventricles are the first to stop beating, then the left auricle stops, and finally—sometimes after more than half an hour—the right auricle comes to a standstill. For this reason the right auricle has been called the *ultimum moriens.*

After the auricular contractions have ceased, careful observation will reveal, even more than an hour after the heart has been separated from the body, a small circumscribed area of activity at thejunction of the superior vena cava with the right auricle. In this area, as will be explained later, there is a small mass of myocardial

[1] Kisch, B., and J. Bardet, "Electron Microscopic Histology," Brooklyn Medical Press, New York, 1951: Kisch, B., *Exper. Med. & Surg.*, **9**, 333, 1951.

tissue that is a vestigial equivalent of the venous sinus of fishes and amphibians. In these animals the sinus is also the cardiac segment with the highest rhythmicity.

In the lower vertebrates the heart has greater rhythmicity than in mammals. The heart of a fish or an amphibian will continue to beat regularly for several minutes, and sometimes hours, after it has been separated from the body. The mammalian heart subjected to this treatment will beat only a few times with all its cavities contracting in a coordinated sequence.

The activity of the isolated heart can be prolonged, even in mammals, by means of special techniques that assure the circulation of nutrient fluids through the heart. Defibrinated blood, Locke's fluid, or other fluids (to be mentioned at the end of this chapter) are used for this purpose. A mammalian heart, including that of man, can be kept beating for several hours, and amphibians' hearts for several days.

Because of this property of rhythmicity, the heart is automatically and periodically stimulated into activity. This is sometimes called the "chronotropic" property of the heart (Greek *χρονος*, time, and *τρὸπειν*, to turn), referring thus to the fact that it marks the time or pace of the heartbeat.

Conductivity. The stimulus that activates the cardiac muscle has its origin in a circumscribed area, but it spreads throughout the heart muscle thanks to its conductivity—a property of the myocardial fiber itself, as was demonstrated by Engelmann.[1]

Conductivity is a property of all the heart muscle, but it is especially developed in the bundle of His and its branches and in Purkinje's tissue.

The excitatory state is transmitted along the cardiac muscle in a way similar to that by which a nerve impulse is propagated along a nerve fiber. There is conduction without decrement (see Chap. 68). If the vitality of the tissue is diminished in any place, whatever the cause (anoxia, intoxication, pressure, inflammation), the excitatory state is transmitted at a lower speed; if the abnormal process is sufficiently severe, conductivity will be completely abolished. Successive stimuli cannot spread through the heart unless there is a certain interval between them.

The speed of transmission of the excitatory

[1] ENGELMANN, T. W., *Arch. f. d. ges. Physiol.*, **11**, 466, 1875.

state is dependent on the heart's conductivity; for this reason this is sometimes known as the "dromotropic" (Greek *δρομος*, running) property of the heart.

Excitability. The heart responds not only to the stimulus originated by its own rhythmicity, but also to external stimuli of different kinds. The heart has therefore the property of excitability. Many extraneous agents can act as stimuli; *e.g.*, mechanical (friction, a blow, pinching); electrical (induced and direct currents, a condenser discharge); thermal (heat, cold); chemical; etc.

The heart is not equally excitable during all the phases of its activity. During systole (contraction) the heart becomes inexcitable for a certain period known as the absolute refractory period, but, as the state of contraction ceases, excitability returns. Excitability increases rapidly very early in diastole, reaching a maximum that is maintained until the next beat.

Maximum excitability, *i.e.*, the lowest threshold, is reached after a few oscillations during the phase of rising excitability (relative refractory period), but a phase of supranormal excitability is not observed at any moment[1] (Fig. 17).

In subjects with heart disease, very premature contractions of the ventricle, *i.e.*, extrasystoles with QRS complexes occurring before the T wave of the preceding contraction has ended (see Chap. 16), have been observed. This phenomenon has been interpreted as proof of the existence of a period of supranormal excitability.[2]

This continuous variation in excitability makes a quantitative estimation of this property extremely difficult, as it is not easy to determine it at exactly the same moment of different cardiac cycles, a necessary condition for making valid comparisons between several observations. This is particularly true when it is necessary to measure the effect on cardiac excitability of drugs and other agents capable of changing excitability.

Between the moment at which the stimulus acts and the response of the heart there is a brief interval known as the latent period. In the dog it is approximately 30 msec. at the moment of the cycle when excitability is at its highest, but

[1] ORÍAS, O., C. MCC. BROOKS, E. E. SUCKLING, J. L. GILBERT, and A. A. SIEBENS, *Am. J. Physiol.*, **163**, 272, 1950.

[2] SMIRK, F. H., *Brit. M. J.*, **11**, 23, 1949.

it is more prolonged during the relative refractory period, increasing as the stimulus is applied nearer to the absolute refractory period. Stimuli applied close to the end of the absolute refractory period may have a latency of nearly 150 msec. For this reason, however early in the cycle
FIG. 17. Excitability of the ventricle in the dog. Abscissa: time, in milliseconds, between the stimulus provoking a beat and the test stimulus. Ordinate: intensity, in milliamperes, of test stimulus. Threshold for test: rectangular shocks of 0.1 msec. duration (dot-dash line), of 6 msec. (broken line), and of 13 msec. (solid line). 1, absolute refractory period; 2, relative refractory period; 3, phase of complete recovery of excitability. (*Orías, O., et al., Am. J. Physiol., vol. 163, p. 272, 1950.*)

a stimulus is applied, the response tends to occur at approximately the same moment, *i.e.*, toward the end of the relative refractory state, and there is no way of obtaining it earlier (Orías *et al.*). The relative refractory period is in fact *relative*, because a response can be obtained if a sufficiently strong stimulus is applied; in a certain sense, however, it is an *absolute* refractory period, because until it is ended there is no response.

Figure 17, designed with data taken from one of many experiments, shows that the myocardium is in the absolute refractory phase only during the first moments of systole, as can be seen if very strong stimuli are applied. By the time the heart enters into diastole, excitability has been almost completely recovered. Using stimuli of maximal strength, the absolute refractory period becomes longer if the duration of the stimulus is shortened (Fig. 17, 1, 1*a*, and 1*b*). The absolute refractory period is prolonged at the expense of the relative refractory period.

Changes in excitability cause variations in the threshold, *i.e.*, the minimum strength of stimulus needed to obtain a response. For this reason this is sometimes called the "bathmotropic" (Greek βαθμος, threshold) property of the heart.

Contractility. In response to the stimulus originated by its own rhythmicity, or to an external stimulus, the heart contracts.

Contractions due to the heart's rhythmicity are the spontaneous beats of the heart, and their succession is known as the cardiac rhythm.

External stimuli provoke a response only after the absolute refractory period has ended. The forced contraction so originated is called a premature beat or extrasystole.

Contractility is also known as the "inotropic" property of the heart (Greek ινος, fiber).

EFFECTS OF STIMULATING AGENTS ON THE MYOCARDIUM

Some special features of the response of the cardiac muscle fiber to different stimuli will be considered under this heading. The most convenient, and most frequently used, stimulus is an induction shock from an induction coil. The spontaneous heartbeat interferes with the experimental observation; therefore an amphibian heart is used, in which the beat is stopped by placing a tight ligature on the sinoauricular junction. Strips cut from mammalian hearts can also be used. All the phenomena described in the
FIG. 18. Apparatus for obtaining a suspension cardiogram

following paragraphs can be demonstrated with a very simple apparatus (Fig. 18).

The "all-or-nothing" law. When a skeletal muscle is stimulated with a series of stimuli of increasing strength, the following phenomena are observed:

1. A very weak stimulus does not provoke a response.
2. On progressively increasing the strength of the stimulus, at a certain strength a very weak contraction will be observed. This is the minimum or threshold stimulus.
3. If the strength of the stimulus is further increased, the muscle responds with contractions of increasing strength, until a maximum is reached. Any further increase above this maximum stimulus does not provoke an increase in the strength of the contraction (Fig. 19).

The same experiment performed with cardiac muscle does not give exactly the same results. The stimulus, in this case, must also reach a minimum strength to provoke a response, but once the threshold has been attained, however much the strength of the stimulus is increased, the heart responds with contractions of constant strength (Fig. 19). The heart responds to the "all-or-nothing" law (Bowditch, 1871),[1] because when the stimulus has a threshold strength, the heart gives the maximum response.

Skeletal muscle
Myocardium
1 2 3 4 5 6
FIG. 19. The "all-or-nothing" law. The myocardium (cardiac muscle) responds with a maximal contraction, and the skeletal muscle with a submaximal contraction, to the threshold stimulus (2). To obtain a maximal contraction from the skeletal muscle the strength of the stimulus must be increased (4). With a subliminal stimulus neither the cardiac nor the skeletal muscles respond (1).

This particular form of response observed in cardiac muscle is due to the fact that all its fibers constitute a syncytium, and therefore the excitatory process is always propagated throughout the whole heart. In skeletal muscle, as the strength of the stimulus is increased, the excitatory state is propagated to a wider area and stimulates a larger number of fibers. The strength of the response depends on the number of fibers stimulated; therefore it will be greater as the stimulus is stronger. Individual muscle fibers also respond to the "all-or-nothing" law (see Chap. 66).

[1] BOWDITCH, H. P., *Ber. Sächs. Ges.*, **23**, 652, 1871.

1 2 3 4 5
FIG. 20. Latent addition and "staircase phenomenon." Diagram of a suspension cardiogram. 1, one subliminal stimulus evokes no response; 2, two subliminal stimuli with an appropriate interval between them provoke a contraction (latent addition); 3, 4, and 5, stimulation with stimuli of constant strength at adequate intervals has produced increasingly greater responses ("staircase phenomenon").

Summation of stimuli. If a stimulus is below the threshold strength it will not provoke a response (subliminal stimulus), but if it is repeated two or more times at adequate intervals, a contraction may be observed. This is known as latent addition or summation of stimuli (Fig. 20). The same fact is observed in skeletal muscle and other tissues (see Chap. 66).

The staircase phenomenon. When a heart that has been at rest for some time is excited by a series of stimuli of threshold (or above-threshold) strength, repeated approximately every 10 sec., the three or four contractions first observed are of increasing magnitude. If horizontal lines at the level of the summit of each contraction curve are traced and joined by vertical lines, a staircase of three or four steps results (Fig. 20); hence the name of "staircase phenomenon" given to this observation.

The cause of this increasing response to a stimulus of constant strength is not known. It has been attributed to the accumulation of metabolic products resulting from the preceding contraction, which would place the muscle in condition to respond more vigorously.[1]

[1] DALE, A. S., *J. Physiol.*, **75**, 1, 1932.

If a longer interval (about 15 sec.) is allowed between the stimuli, the contractions are all of equal strength; there is no "staircase."

Circular excitation. Mines[1] observed some peculiar facts in muscular rings cut out from the ventricle of amphibians. These observations have been of great importance in the interpretation of certain functional anomalies of the cardiac contraction. Moderate pressure was applied on one point of the ring and the muscle was stimulated in the neighborhood (on either side) of the blocked area. A wave of contraction was thus initiated at the stimulated spot and transmitted toward the parts that were not blocked. After the wave had been started the block was removed. When the contraction wave, having traveled around the ring, arrived at the previously blocked area, this area was stimulated by the wave and transmitted the excitatory state to parts of the ring which had already been contracted. In this way the wave continued to travel around the ring for a relatively long time. This particular type of excitation and contraction is known as a "circus movement."

FIG. 21. Circus movement. A wave of excitation (black) passes through a ring of muscle, leaving behind it a refractory state (stippled). The arrow marks the direction in which the wave spreads. (*After T. Lewis.*)

The cause of this movement is the following: The blocked area prevents the spread of excitation in one direction, so the excitatory state can be transmitted only in the other direction. If the block is removed after the wave of contraction has progressed a short way, it cannot be excited by a "backward" spread of excitation because it is protected by an area that is still in a partially refractory state as a result of the passage of the wave. To stimulate the previously blocked area, the wave must travel around the ring. By that time the refractory state of the areas that have already contracted will have ended, so they will be in condition to respond to the excitation transmitted through the previously blocked area. The wave of contraction thus travels around the ring several times because it finds tissue in an excitable state before it and leaves tissue in a refractory state behind it (Fig. 21).

[1] MINES, G. R., *J. Physiol.*, **46**, 349, 1913.

Mayer[1] had made a similar observation in muscular rings taken from jellyfishes.

Fibrillation. In certain conditions the heart muscle fibers do not contract as in a normal beat, *i.e.*, more or less simultaneously. The contraction of the fibers is not coordinated; therefore the whole muscle does not contract, but some fibers, or groups of fibers, are in contraction, and other fibers, or groups of fibers, in relaxation (Fig. 22). The heart muscle seems to tremble or to be in a state of continuous convulsive movement. If a large part of the heart is involved, *e.g.*, all the fibers of the ventricles in a dog, this form of activity, known as fibrillation, has a tendency to persist. If the cardiac mass is small (a fragment of ventricle, or a small heart) fibrillation disappears after a few seconds. In small fragments of heart (1 gm. or less), fibrillation cannot be provoked.[2]
FIG. 22. Diagram illustrating normal contraction of the heart (above) and fibrillation (below). Above, the black bands represent the systole with all the fibers contracting simultaneously; the white bands represent the diastole with all the fibers relaxed. Below, there are fibers in systole (in black) and others in diastole (in white) at all times.

Fibrillation can be produced in several ways. The simplest is to stimulate the heart with a tetanizing induced current, or an alternating current of sufficient intensity. Isolated electrical stimuli in certain conditions can also provoke fibrillation, and the same result can be obtained

[1] MAYER, A. G., "Papers from Tortugas Laboratories," **1**, 115, Carnegie Institution, Washington, D.C., 1908.
[2] MARTÍNEZ, C., *Medicina, Buenos Aires*, **4**, 109, 1944.

with other stimuli: mechanical (pinching, blows), thermal (heat, cold), and chemical (caustic substances). The obstruction of a main branch of one of the coronary arteries is a frequent cause of fibrillation. Excessive doses of several drugs, such as digitalis, adrenaline, some of the anesthetics, and potassium, have the same effect.

There has been much discussion on the nature and mechanism of fibrillation, and as yet there is no unanimous agreement on the subject. Probably fibrillation is a form of cardiac activity caused by a particular condition in which the excitability and conductivity of the cardiac fibers are not homogeneous. Its initiation depends on the moment of the cardiac cycle at which the stimulus is applied. If the stimulus arrives when all the fibers are equally excitable and their conductivity is the same, they will contract simultaneously and a normal heartbeat will occur. On the contrary, if the stimulus is applied when only part of the fibers are excitable and can conduct the excitatory process, while others are in a refractory state, owing to the complex structure of the heart muscle, there will be a network of excitable fibers interwoven with a network of refractory fibers. Some of the fibers will then contract while others remain quiescent, *i.e.*, fibrillation will be provoked. The condition will have a tendency to persist, because there will always be some active fibers capable of transmitting the excitatory process to others that have just recovered from the refractory state.

Wiggers' work[1] is an important contribution toward solving the problem of the production and nature of fibrillation. He and his collaborators have shown that one isolated stimulus can provoke fibrillation if it acts at a particular moment of the cardiac cycle. This moment, appropriately called the "vulnerable phase" of cardiac activity, coincides with the phase of fluctuating excitability of the relative refractory period,[2] when some of the cardiac fibers are still refractory and others have more or less recovered their excitability.

Nutritional disturbances limited to certain areas of the heart produce a condition of heterogeneity or disparity between them and thus become factors that cause fibrillation. A similar effect is produced by several drugs and toxic substances, because they affect unequally the properties of the different fibers.

[1] WIGGERS, C. J., *Bol. Acad. nac. de med. de Buenos Aires*, 567, 1938; *Am. Heart J.*, **20**, 399, 1940.

[2] BROOKS, C. McC., O. ORÍAS, J. L. GILBERT, A. A. SIEBENS, B. F. HOFFMAN, and E. E. SUCKLING, *Am. J. Physiol.*, **164**, 301, 1951.

Prinzmetal and his associates[1] have applied cinema techniques to the study of fibrillation. If films obtained at a rate of 3,000 pictures per second are projected at a normal rate of 16 pictures per second, a very slow-motion effect is obtained (speed is reduced 180 times). Even thus fibrillation, according to Prinzmetal and his associates, appears as a completely disorganized activity, which proceeds without rhyme or reason, spreading to all the contractile elements of the auricle and different from all other normal or abnormal functional states of the heart. At no time did they observe anything remotely similar to circular excitation.

Flutter. In this form of activity the heart muscle shows a series of contractions, one following immediately after the other. Excitability and conductivity are in such a condition that the excitatory process, after having provoked the contraction of a fiber, can immediately stimulate the same fiber, because the refractory state has disappeared. It is a condition similar to the circus movement already described. Prinzmetal and his associates conclude, however, from their studies with the cinema technique mentioned earlier that auricular flutter is due to the periodic discharge of impulses of high frequency from a single focus, which spread simultaneously in all directions.[2] They deny, therefore, the existence of a circus movement.

THE TONUS OF THE MYOCARDIUM

It is difficult to determine whether cardiac muscle has true tonus. At any rate it does not have a tonus actively produced and completely dependent on nervous activity, comparable with the tonus of skeletal muscles. The innervation of the heart, provided by the autonomic nervous system, differs considerably from the somatic innervation of skeletal muscles. Moreover, in the diastole there are no electrical phenomena denoting activity, while even at rest there are electrical variations in the skeletal muscles, corresponding to their tonic activity.

[1] PRINZMETAL, M., E. CORDAY, I. C. BRILL, R. W. OBLATH, and H. E. KRUGER, "The Auricular Arrhythmias," Charles C Thomas, Springfield, Ill., 1952.

[2] *Ibsd.*

According to Starling[1] what is usually called the "tonus" of the heart is synonymous with its physiologic condition. A heart in good condition has a high tonus and empties itself almost completely at each systole even when it receives a large amount of blood during diastole. A heart with a low tonus is in a condition of fatigue. It is dilated at the end of systole and still contains a large amount of residual blood.

Table 15. Percentage Composition of Physiological Saline Solutions

	Ringer (frog)	*Locke*	*Tyrode*	*Dale*	*Lovatt-Evans**
Water	100.0	100.0	100.0	100.0	100.0
NaCl	0.65	0.9	0.8	0.9	0.85
KCl	0.014	0.042	0.02	0.042	0.042
$CaCl_2$	0.012	0.024	0.02	0.024	0.024
$NaHCO_3$	0.02	0.01–0.03	0.1	0.05	
NaH_2PO_4	0.001	....	0.005		
$MgCl_2$	....	....	0.01	0.0005	
Glucose	0.2	0.1–0.25	0.1	0.05	0.1
Na_2HPO_4	....	....	....	....	0.06

* 0.02–0.06 cc. of normal H_3PO_4 is added to each 100 cc.

According to Wiggers,[2] the tonus of the myocardium is the equivalent of its distensibility. On receiving the venous inflow at a given pressure, a heart with a high tonus is distended less, and therefore receives a smaller volume of blood, than one with a low tonus. The idea is here implicit that the condition of the cardiac fiber regulates its distensibility. It is nevertheless very difficult to demonstrate changes in the distensibility of a normal myocardium.

EQUILIBRATED SALT SOLUTIONS

Many years ago Ringer[3] first demonstrated the great importance of certain salts for the maintenance of rhythmicity and other properties of the heart muscle. Simple saline solutions cannot keep the heart beating for any length of time. A fragment of tortoise heart placed in 0.7 per cent NaCl solution begins to beat rhythmically, but soon the contractions weaken and finally they cease, the heart fragment remaining flaccid and completely relaxed. If now a very small quantity of $CaCl_2$ is added to the solution, the heart again begins to beat, but gradually relaxation is less complete after each contraction, until finally the fragment stops beating, remaining tonically contracted. If a very small amount of KCl is now added, rhythmic contractions again appear, and the fragment can continue to beat for several hours, although the solution does not contain any nutritive substance capable of providing energy for the contracting muscle. The mechanism by which the different ions act on the heart is still unknown.

Since these now classic experiments were reported, many other experiments have been made in which the isolated heart and other organs have been kept active and in a good condition. The proportions of Na^+, Ca^{++}, and K^+ vary according to the particular conditions of the organ studied. In the case of tissues or organs of homoiothermic animals, it is also necessary to keep them at a temperature of 38 to 39°C. and to oxygenate the perfusion fluid. Locke[1] showed that by adding glucose it was possible to keep the heart beating for a much longer time, and even to revive the activity of a heart which had ceased to beat in a saline solution free of glucose. Sodium lactate can replace glucose with advantage.

Besides the ionic equilibrium discussed above, a perfusion fluid must have an adequate osmotic pressure and acid-base equilibrium, and it must be at a temperature suitable for the tissue examined.

CHAPTER 12

The Shape, Consistency, Movements, and Volume of the Heart

THE HEART IS a hollow organ, with elastic walls of unequal thickness, and with compartments, the contents of which vary in amount from one moment to another.

The beating heart can be observed directly in poikilothermic and homoiothermic (see Chap. 48) animals. The former have the advantage of being easier to handle, and their hearts can be exposed with a very simple technique. Frogs, toads, and tortoises are frequently used to demonstrate the heartbeat; observation is made easier by the low rhythm and relatively slow movements. Direct observation of the beating heart in homoiothermic animals is not so simple, as special methods are required, but it is of great interest because the results can be more directly applied to man. Rabbits, cats, and dogs are most frequently used. The animal is anesthetized, and the thorax is opened. Artificial respiration must be applied before the thorax is opened, by rhythmically inflating the lungs with a bellows or an air pump, and must be kept up throughout the experiment. The pericardium is opened, and by sewing it onto the chest, an ample breach is made which exposes the heart. Direct observation of the human heartbeat was first recorded by Harvey, in the now historic case of the Earl of Montgomery, who had a malformation that exposed the heart. In the course of thoracic operations, direct observations of the heart have also been made.

A semidirect observation can be made by means of x-rays. By radioscopy it is possible, without opening the thorax, to observe the cardiac shadow and its variations during the course of the heartbeat.

Visual or tactile inspection of the heart does not give much information, because of the short duration and the rapidity of the changes that take place. Graphic registration must be used for accurate and detailed observation. Many methods have been devised by the careful application of mechanical principles; these will be described in the course of the following chapters.

DIRECT OBSERVATION OF THE HEARTBEAT

When the mammalian heart is directly observed *in situ*, the most prominent features are the contraction of the auricular appendages during auricular systole and the contraction of the ventricles with a slight rotation toward the right along the longitudinal axis. The ventricular volume does not vary conspicuously when observed with the naked eye, nor are there any changes in color. There is a change in the consistency of the ventricular wall, which is more marked in the right ventricle because its walls are not so thick as those of the left; in diastole they are dilated and flaccid, but become rounded and hard in systole. The changes in consistency can be readily appreciated by grasping the organ. The movements and changes in consistency of the heart cause the apex beat, which will be described later.

To obtain a simple record of the contraction of the mammalian heart, two pairs of connected Marey tambours can be used; one pair is tied to the auricle and the other to the ventricle, so that when the heart contracts the pressure rises within the tambour. This rise of pressure is communicated by a rubber tube to the other tambour of the pair, which records the rise on a kymograph. This method gives information only as to the sequence of the auricular and ventricu-

lar systoles, their regularity, and if a time marker is added, the heart rate.

THE PHASES OF THE CARDIAC CYCLE

The method described above does not permit the registration in detail of all the events in the cardiac cycle. Accurate knowledge has been obtained by correlating several aspects of the activity of the heart (Fig. 23). The different records that have afforded a base to delimit and recognize the phases of the cardiac cycle will be considered in detail further on, but it is convenient to enumerate these phases here, as they will be frequently referred to in the following paragraphs.

The succession of coordinated movements that takes place in the heart from the beginning of an auricular systole to the beginning of the following auricular systole constitutes a cardiac cycle. The three most important components of the cycle are, in order of appearance, (*a*) auricular systole, or presystole; (*b*) ventricular systole; (*c*) ventricular diastole.

Each one of these divisions comprises several phases, which correspond to well-defined events in the activity of the heart. For special purposes these phases can be considered as made up of subphases.

Auricular systole or *presystole* has an average duration in man of 0.11 sec. It is frequently considered as the last phase of ventricular diastole. Auricular contraction is not essential for the maintenance of an adequate circulation. Many persons with auricular fibrillation live for years without necessarily suffering from circulatory insufficiency.

Ventricular systole begins immediately after auricular systole has ended. If a low heart rate prevails there may be a short pause, the so-called "intersystolic interval," between the contractions of the auricle and the ventricle. Two well-defined phases can be distinguished in ventricular systole. During the first phase ventricular pressure increases, but the contents of the ventricle are not altered because the semilunar valves are kept closed by the pressure in the arteries, and the auricular-ventricular (A-V) valves close almost immediately after the ventricle begins to contract. During the second phase intraventricular pressure reaches and rises above the pressure in the arteries; the semilunar valves are therefore opened and blood flows from the ventricles into the arteries. The first phase is called the *isometric contraction phase* (Greek ἴσος, equal, and μὲτρον, measure), because the ventricular volume remains constant. The second is called the *ejection phase*, because the ventricle evacuates its contents; it extends
Fig. 23. Phases of cardiac activity. *A*, intraventricular pressure; *B*, aortic pressure; *C*, ventricular volume; *D*, intra-auricular pressure; *E*, phonocardiogram; *F*, phlebogram; *G*, electrocardiogram; 1, auricular systole or presystole; 2, isometric contraction; 3, maximum ejection; 4, reduced ejection; 5, protodiastole; 6, isometric relaxation; 7, rapid filling; 8, diastasis.

from the opening to the closure of the semilunar valves, which occurs as soon as the ventricles begin to relax.

Two subphases have been distinguished in the isometric contraction phase: the *entrant phase* and the *massive-contraction phase*. During the former, the fibers that constitute the ventricle enter successively into contraction and intraventricular pressure rises slowly; during the latter, when the excitatory state has spread to all the fibers, they are contracting simultaneously and intraventricular pressure rises rapidly. The whole isometric contraction lasts about 0.05 sec.

During the ejection phase, three subphases can be distinguished. Immediately after the semilunar valves

are opened there is a short period during which only a minimum amount of blood is ejected because of the inertia of the mass of blood in the large arteries (*minimal ejection subphase*). A subphase of *maximal ejection* follows, during which the greater part of the blood in the ventricles is discharged into the arteries.
FIG. 24. Cardiometer.

Finally there is a subphase of *reduced ejection*. The whole ejection phase lasts 0.22 sec., the minimal eiection subphase 0.01 sec., maximal ejection subphase 0.08 sec., and reduced ejection subphase 0.13 sec.

Ventricular diastole commences when the ventricular musculature relaxes. It comprises four phases: protodiastole, isometric relaxation, rapid inflow, and retarded inflow or diastasis. The first effect of ventricular relaxation is a drop in pressure within the ventricle and the closure of the semilunar valves, marked by a sharp notch (incisura) in the aortic pressure curve. This *protodiastolic phase* lasts 0.04 sec. and its end coincides with the second heart sound. It is usual, therefore, to consider this sound as indicating the end of systole and the beginning of diastole.

Immediately after the closure of the semilunar valves, the A-V valves are still closed, and they remain so for about 0.08 sec. During this interval the ventricles relax without any significant change in volume. This phase is known as the *isometric relaxation*.

Following this phase the A-V valves open and blood accumulated in the auricles during ventricular systole, protodiastole, and isometric relaxation passes into the ventricles. At first a large amount of blood flows into the ventricle (*rapid inflow*), but later it flows at a lower rate, and continues to do so up to the end of the heart cycle. Rapid inflow lasts about 0.11 sec., and *retarded inflow*, or *diastasis*, about 0.19 sec.

In a resting subject, with a heart rate of 75 beats per minute, each cycle lasts about 0.8 sec.; ventricular systole has a duration of 0.3 sec., and ventricular diastole lasts 0.5 sec.

VENTRICULAR VOLUME

Detailed observation of the changes in ventricular volume gives considerable information on many aspects of cardiac function. It must be made with adequate recording apparatus, and preferably by optic registration.

Changes in ventricular volume are studied experimentally by means of the plethysmographic method, following François Frank's technique, in which the heart is introduced into a glass or metal vessel closed by a rubber diaphragm up to the A-V junction. The heart must fit snugly, but without being compressed by the rubber (Fig. 24). Changes in pressure caused in the plethysmograph by the heartbeat are transmitted through rubber tubing to a Marey recording tambour, or to a Frank segment capsule for optical recording. A rise in the curve records an increase in volume; a decrease in volume is recorded by a drop.

Even with the most perfect apparatus it is difficult to obtain ventricular volume curves completely free from artefacts. At the beginning of systole the whole heart has a tendency to penetrate farther into the cardiometer, and thus a rise in pressure is caused that does not correspond to a change in volume. Frequently the first part of the pulmonary artery is enclosed in the plethysmograph; thus, especially at the beginning of the ejection phase, an artefact caused by changes in the volume of this artery is introduced into the ventricular volume curve. Also during isometric relaxation, a small increase in ventricular volume is sometimes recorded, which is attributed to the entrance of blood into the intramuscular branches of the coronary arteries. As these artefacts occur at definite moments, by careful analysis their effects can be properly evaluated.

Ventricular volume is conveniently recorded simultaneously with aortic or auricular pressures so as to have points of reference in the analysis of the curves.

Cyclic changes in ventricular volume. In each cardiac cycle there are changes in volume due to the emptying and filling of the ventricles. Figure 25 reproduces ventricular volume and aortic pressure curves recorded simultaneously with a Frank segment capsule and a Wiggers optical manometer respectively. In the following description, the letters in parentheses refer to the segments marked on the curves.

FIG. 25. Simultaneous records of ventricular volume (upper tracing) and aortic pressure (lower tracing) in the dog. Time in 0.2 sec.: *a-b*, presystole; *b-c*, isometric contraction; *c-d*, maximum ejection; *d-e*, reduced ejection; *e-f*, isometric relaxation; *f-g*, rapid inflow; *g-a*, diastasis.

During auricular systole (*a-b*) the ventricular volume increases more or less according to the length of the preceding diastole; the longer the diastole, the smaller the amount of blood contributed by auricular systole to the filling of the ventricle. In a heart beating at a normal resting rate, this contribution is not very important. Neither is it necessary, as is proved by cases of auricular fibrillation with good circulatory conditions.

During isometric contraction (*b-c*), *i.e.*, between the beginning of ventricular systole and the opening of the semilunar valves, there are no changes in ventricular volume because all the heart valves are closed, so that blood can neither enter nor leave the ventricles. A small rise in the volume curve is nevertheless almost always recorded; this artefact is due to the tendency of the ventricle to penetrate farther into the cardiometer, as has already been mentioned.

During the ejection phase (*c-e*) ventricular volume decreases, at first rapidly, the tracing dropping almost vertically (*c-d*), and then more slowly, so that the tracing becomes almost horizontal (*d-e*). This decrease in volume is due to the ejection of blood into the arteries, at first rapidly (maximum ejection) and then at a lower rate (reduced ejection).

Between the closing of the semilunar valves and the opening of the A-V valves (*e-f*), *i.e.*, during isometric relaxation, when blood does not enter or leave the ventricle, the curve rises slowly. This is attributed to the entrance of blood into the coronary arteries within the ventricular walls, which are compressed during the systole by the contraction of the myocardium.

The opening of the A-V valves causes a rise in the curve, which at first takes place rapidly (*f-g*) and then more slowly (*g-a*). The ventricle fills in two phases: one of rapid inflow and then another of retarded inflow, or diastasis. Auricular systole follows the phase of diastasis and begins a new cycle.

The diastolic size of the heart is recorded at the end of diastole, *i.e.*, at the moment of maximum ventricular volume. The systolic size is recorded at the end of ventricular systole, *i.e.*, when the ejection phase has ended and the ventricular volume is at its minimum.

The mean ventricular volume. Besides the changes in ventricular volume that occur in the course of the cardiac cycle, it is interesting to note the variations in volume through a series of cycles, as in certain physiologic circumstances

the heart in the successive cycles does not have the same systolic or diastolic size. The mean ventricular volume must be considered when following these changes through several cycles. An idea of this mean volume can be obtained from the general direction of the plethysmogram. The mean ventricular volume is an abstract idea; it would correspond to the line joining the points representing the average volume of the ventricle during each cycle. Heart rate, venous return, and peripheral resistance to blood flow are factors that modify the mean cardiac volume. Changes in the heart rate cause variations in the duration of the diastole. As the heart rate increases, the filling time of the ventricles is shortened. If there is moderate tachycardia, the shortening of the diastole affects only the last moments of retarded inflow or diastasis; therefore the ventricular volume is only slightly reduced. If there is considerable tachycardia, shortening of diastole affects the phase of rapid inflow and thus impairs ventricular filling; the diastolic size decreases and consequently the mean ventricular volume diminishes. Bradycardia has the opposite effect on diastolic size and mean ventricular volume.

Changes in venous return produce parallel changes in the mean ventricular volume. An increase in venous return increases the mean ventricular volume, and vice versa.

Changes in the peripheral resistance, which must be overcome by the heart to eject the blood, also act on the mean ventricular volume. An increase in resistance increases ventricular volume; diastolic size is mainly responsible for the change. Variations in the mean ventricular volume are therefore approximately proportional to the variations in venous return and peripheral resistance; but it does not follow that there is a strictly linear relation between these variables.

Electrokymography. Fluorocardiography. If a photoelectric cell is applied on the margin of the shadow cast by the heart on the x-ray fluoroscope, it is possible to register the movements of the heart during the cardiac cycle. This procedure was first called electrokymography[1] and later fluorocard ography.[2] The current arising in the photoelectric cell is recorded by means of a string galvanometer such as is used in electrocardiography. The photoelectric cell is placed in a closed box, with a slit through which it is stimulated. It can be placed on any part of the margin of the shadow cast by the heart or the large arteries. Records obtained by placing the cell on the margins of the right and left auricles, the aorta, or the pulmonary artery are similar to the corresponding pressure records; those of ventricular movements are similar to volume records.[1] The procedure is not, however, exempt from artefacts.[2]

DIASTOLIC SIZE AND STRENGTH OF CONTRACTION

The law of the heart. One of the most remarkable features of cardiac physiology is the way in which the ventricle responds to an increase in its contents. This capacity to respond is of primary importance for the adaptation of the heart to different circulatory conditions. When the contents of the ventricle increase, whatever the cause, the cardiac fibers lengthen and there is a more vigorous contraction; intraventricular pressure increases more rapidly, isometric contraction is shortened, the ejection phase is lengthened, and the velocity of ejection increases. This response is known as Starling's law of the heart. As the load of the heart increases, so does the strength of its contraction, but only up to a critical limit, above which contractions become progressively weaker. In this condition of circulatory decompensation the heart is not sufficiently emptied at each systole, and it dilates progressively without a corresponding increase in the strength of its contraction. Catheterization of the human heart has shown that in man the right ventricle also responds to Starling's law of the heart.[3]

When ventricular dilatation occurs within the limits of the law of the heart, it is said to be a tonogenic dilatation (Moritz). When the capacity of adaptation of the heart has been surpassed and the myocardium

[1] LUISADA, A. A., and F. G. FLEISCHNER, *Proc. Soc. Exper. Biol. & Med.*, **66**, 436, 1947. MEDNICK, H., J B. SCHWEDEL, and P. SAMET, *Circulation*, **2**, 250, 1950; SALANS, A. H., J. A. SCHACK, and L. N. KATZ, *Circulation*, **2**, 900, 1950.

[2] ZINNGER, H. F., C. F. KAY, and J. M. BENJAMIN, *Circulation*, **2**, 197, 1950.

[3] LAUSON, H. D., A. COURNAND, and R. A. BLOOMENFIELD, *J. Clin. Investigation*, **25**, 913, 1946.

does not respond to an increase in load by a more vigorous contraction, it is said to enter into myogenic dilatation (Moritz).

Whether the greater length of the fiber, caused by the increased volume, is the cause of the more vigorous contraction, as Starling believed, or whether this is due to an increase in initial tension produced by the lengthening of the fiber, is a subject still under debate. This discussion is mainly of academic interest, because under ordinary conditions, whenever the fiber is lengthened its tension is increased.

Starling and his associates also found that an increase in the oxygen consumption of the myocardium accompanied the increased diastolic volume of the ventricles responsible for the more vigorous contraction. This metabolic increase, within certain limits, is proportional to the elongation of the fibers.

Hypertrophy of the heart. In certain conditions the heart can become totally or partially enlarged, because of a more or less considerable increase in the mass of its fibers.

Hypertrophy results from persistent diastolic overloading with moderate distention of the cardiac fibers, due to incomplete evacuation, as in cases of valvular stenosis or increased peripheral resistance, or to the reception of abnormal additional loads, as in cases of valvular insufficiency.

Moderate distention increases the strength of systole and is therefore the first compensatory factor in response to the abnormal condition. Probably it is also the initial stimulus of the metabolic process that produces cardiac hypertrophy. This hypertrophy is a more permanent compensatory mechanism, which restores to a certain extent the reserves that have been depleted.

Cardiac hypertrophy is prominent in certain pathologic conditions, but it is also a physiologic reaction. At birth both ventricles have approximately the same development, but when the pulmonary circulation is established and the ductus arteriosus and Botallo's foramen are closed, each ventricle has to fulfill a different task; the left ventricle must overcome a resistance far greater than that encountered by the right one. Gradually the left ventricle develops more than the right; in a normal adult its walls become four to five times as thick. The mechanism of this physiologic hypertrophy is probably the same as that of pathologic hypertrophy.

MYOCARDIOGRAPHY AND MYOCARDIOGRAMS

The contraction of the heart fibers can be studied in the heart beating *in situ*, or in the isolated heart, by means of a recording device known as a myocardiograph. Records so obtained are called myocardiograms. There are several types of myocardiograph, but each consists essentially in a pair of lever arms articulated together so that the shortening and lengthening of the cardiac fibers, to which they are attached, separates or approximates them; this movement then acts on a suitable recording system. The records obtained are frequently altered by artefacts, and their interpretation requires considerable experience.

Cinefluorographic angiocardiography. A substance which is opaque to x-rays, *e.g.*, a 70 per cent solution of diodrast, is injected into the jugular vein in dogs, and subsequent events are recorded by means of motion pictures of the fluoroscopic image of the heart, taken for periods of 10 to 14 sec. This procedure shows that diastolic filling of the ventricle takes place more rapidly than systolic emptying, and that a certain amount of residual blood remains in the ventricle at the end of systole. Auricular contraction produces little change in the diastolic size of the ventricle.[1]

A similar technique has been applied in man. This consists in injecting diodrast directly into the cavities of the heart by transthoracic puncture.[2]

THE APEX BEAT

If the anterior thoracic wall at the level of the fourth or fifth intercostal space, slightly medial to a vertical line passing through the nipple, is palpated, a sensation will be felt as if the thoracic wall were lifted at each heartbeat. This is known as the apex beat.

In pathologic conditions, owing to displacement, hypertrophy, or dilatation of the heart, the place and sometimes the nature of the apex beat are changed.

The sensation perceived is due to the sudden hardening of the myocardium and the changes in position caused by the ventricular systole (R. Tigerstedt).

[1] Rushmer, R. F., and N. Thal, *Circulation*, **4**, 219 1951.

[2] Ponsdomenech, E. R., and V. Beato-Nuñez, *Am. Heart J.*, **41**, 643, 1951.

The apex-beat cardiogram. The apex beat can be registered, and the record obtained is known as the apex-beat cardiogram. Marey was the first to obtain this type of record by means of a cardiograph (Fig. 26) connected by rubber tubing with a recording tambour. The form of the curve obtained depends on the location of the button of the cardiograph. If it is placed exactly over the pulsating area, the hardening of the apex is registered; the tracing rises above the base line, and is similar to an intraventricular pressure curve. If the button is not placed exactly above the pulsation, the curve obtained is the equivalent of a cardiac plethysmogram (volume curve), and falls mostly below the base line.

Fig. 26. Marey's cardiograph.

The apex beat can be recorded by the optical method. A small funnel, connected by rubber tubing with a Frank segment capsule, is placed over the apex and the variations in pressure are registered in a photokymograph. Tracings of optically recorded apex beats are given in Figs. 27, 28, and 29. The most important features are

1. An auricular wave due to the distention of the ventricle caused by the blood ejected into it by the auricular contraction.
2. The principal or systolic wave, which shows considerable variations in different individuals or even in the same person according to the location of the receptive funnel or the pressure exerted on it. In some instances it closely resembles an intraventricular pressure curve (Fig. 27); in others, the curve, after an ascending phase of variable length, shows a fall very similar to that of the ventricular volume curve during the ejection phase (Fig. 28). Finally, there may be a blending of both types of curves, giving rise to a considerable number of intermediate varieties (Fig. 29).
3. At the beginning of diastole, corresponding to the rapid inflow phase, there is a more or less clear and rapid rise in the curve, caused by the sudden distention of the ventricle by the blood that enters it when the A-V valves open.

If a very sensitive recording system is used, the vibrations of the heart sounds may appear superimposed on the curve described.

In an apex-beat curve it is possible to recognize auricular systole, the commencement of ventricular systole, sometimes the isometric contraction and ejection phases, the rapid inflow, and the retarded inflow or diastasis.

The apex-beat curve records mainly changes occurring in the left auricle and ventricle, while the venous pulse (to be described later) portrays mainly the activity of the right cavities. Simultaneous records of the apex beat and venous pulse will make it possible to determine the degree of coordination of the activity of the right and left ventricles, and so to establish which ventricle contracts first in cases of ventricular extrasystoles or bundle-branch block.[1]

CARDIOPNEUMATIC PHENOMENA

The thorax, with its semirigid walls, behaves as a plethysmographic chamber which registers changes in ventricular volume and the ejection of blood out of the thorax. There is a slight fall in intrathoracic pressure at each ejection phase of the ventricular systole, especially when the glottis, or the nose and mouth, are closed. These variations of intrathoracic pressure due to the activity of the heart are known as cardiopneumatic phenomena. They can be recorded by connecting the trachea by means of rubber tubing with a Marey tambour or a Frank segment capsule. The curve so obtained is a cardiac volume curve. The subject must give considerable cooperation to obtain good tracings.

FUNCTIONS OF THE PERICARDIUM

The pericardium is a serous membrane which separates the heart from the neighboring

[1] Battro, A., E. Braun Menendez, and O. Orías, *Rev. argent. de cardiol.*, 3, 325, 1937.
FIG. 27. Optical record of human carotid pulse (upper tracing) and apex-beat cardiogram (lower tracing). The apex-beat cardiogram in this case has registered the hardening of the apex and the record resembles that of intraventricular pressure. Note the delay of the carotid pulse with respect to the apex-beat cardiogram. (*Records obtained by Dr. E. Braun Menéndez.*)
FIG. 28. Phlebogram and apex-beat cardiogram. The latter is the equivalent of a record of the heart volume. Note that the descending limb of the *v* wave in the venous pulse (rapid filling) coincides with a rise in the cardiogram. (*Records obtained by Dr. E. Braun Menéndez.*)

viscera. It forms a receptacle closely adapted to the cardiac surface, which is permanently lubricated, thus facilitating the movements of the heart.

The inelastic, resistant fibers of the pericardium protect the heart from sudden and excessive dilatation. The pericardium, on the other hand, can be considerably distended by a force of small intensity if it acts continuously. Thus the capacity of the pericardium can be considerably increased in cases of cardiac hypertrophy, progressive dilatation of the heart, and pericardial effusion.
FIG. 29. Apex-beat cardiogram, phonocardiogram, and electrocardiogram. The apex-beat cardiogram in this case is of the intermediate type, recording first the hardening of the apex and then ventricular volume. (*Records obtained by Dr. E. Braun Menéndez.*)

The pericardium is not indispensable for the normal activity of the heart; it can be completely extirpated without causing any outstanding disturbance.

CHAPTER 13

Pressure Changes in the Heart

CHAUVEAU AND MAREY[1] were the first to obtain records of pressure changes in the heart. Their observations were made on the horse by means of special catheters.

The right auricle and ventricle were explored with a single flexible catheter, the walls of which could not be flattened; at one end it had two rubber balloons sustained by a metal frame. Each one of these balloons was connected separately by rubber tubing with a Marey tambour, which registered the pressure changes on the smoked surface of a kymograph. The catheter was passed down the jugular vein so that the balloon on its end was placed in the right ventricle, and the more proximal balloon in the right auricle.

The left ventricle was explored by means of a metal catheter ending in a rubber balloon, which was passed through the carotid artery and the aorta into the ventricle. This catheter was connected with another Marey tambour. Figure 30 shows a diagram of the apparatus, and Fig. 31 the curves obtained.

Chauveau's and Marey's work is of great historical importance, as it inaugurated an era in the physiology of the circulation. Their results were soon surpassed by those of other workers who used more accurate methods. Their apparatus did not give a faithful record of all the pressure changes, because it could not respond with sufficient speed owing to its inertia; moreover, friction on the recording surface damped the pressure waves and suppressed significant details in the curve.

[1] CHAUVEAU, A., and E. J. MAREY, *Gaz. méd. Paris*, p. 675, 1861. *Compt. rend. Acad. d. sc.*, **53**, 622, 1861; **59**, 32, 1862.

Frank's theoretical and experimental studies led to the construction of instruments of great efficiency. The replacement of levers by a beam of light permitted the use of capsules with very tensely drawn membranes without diminishing the sensitiveness of the apparatus; these responded rapidly, were practically aperiodic, and had no inertia. Frank's optical manometer was later improved by Wiggers, who has applied the method widely in the study of the pressure pulses in different parts of the cardiovascular system.
FIG. 30. Diagram of Chauveau's and Marey's apparatus for registering intracardiac pressure changes.

PRINCIPLES OF MANOMETRIC REGISTRATION

According to Wiggers[1] the requirements of a good manometer are (*a*) that it inscribe a curve that has a sufficient amplitude to show changes in gradient and finer vibrations; (*b*) that it respond without measurable lag; (*c*) that it reproduce the pressure variations correctly as regards amplitude and phasic relations.

[1] WIGGERS, C. J., "The Pressure Pulses in the Cardiovascular System," Longmans, New York, 1928.

The amplitude of the curve depends on the sensitivity of the instrument; *i.e.*, on the relation between the magnitude of its response and the force that provokes it. The sensitivity of an instrument is greater as the force necessary to provoke a response of a certain magnitude is smaller.

The efficiency of an instrument in recording the correct amplitude and phasic relations of pressure changes depends on its dynamic properties—inertia and natural frequency—which condition its capacity to begin and to cease registering without delay.

Recording manometers are periodic systems, and if their dynamic attributes are not adapted to the pressure changes which they must record, the resulting curves will be vitiated by faults due to the inefficiency of the instrument.

To obtain a faithful record the natural frequency of the recording system should be at least five times the frequency of the shortest component of the variation to be registered.

Otto Frank analyzed and correlated mathematically the factors that condition sensitivity and natural frequency of registering systems, and he was able to develop a firm theoretical basis for the construction of manometers of great fidelity. Thus the segment capsule came into use. In this the registering lever is replaced by a beam of light which has no inertia and is absolutely rigid. Frank's segment capsule plays in optical registration the part played by Marey's tambour in the registration on a smoked surface. It is used for optical registration not only in connection with manometers but also, as will be seen later, in other recording systems.
FIG. 31. Cardiac pulses in the horse. O, right auricle; V, right ventricle; P, apex-beat cardiogram; SO, auricular systole (*Chauveau and Marey.*)

Frank's segment capsule is a small hollow cylinder, one end of which is covered by a rubber membrane at a suitable tension, on which a small mirror is attached. The diameter of the cylinder is 7 to 9 mm., and its height less than 1 cm. (Fig. 32). The end covered by the rubber membrane is flattened on one side, so if seen "end on" it appears like a circle from which a segment has been cut off; hence the name of segment capsule. The mirror is attached to the membrane so that one of its edges coincides with the flattened side of the capsule, which thus acts as an axis for the movements of the mirror when the membrane swells out or is depressed by the pressure changes within the system. As the mirror moves, the direction of a beam of light reflected on it changes, and these changes can be recorded on a photosensitive surface that moves in a direction at right angles to that in which the light beam moves. The apparatus that holds and moves the photographic film is called a photokymograph.

The natural frequency of a registering manometer obeys the following law, established by Frank:[1]

$$N = \frac{1}{2\pi}\sqrt{\frac{E'}{M'}}$$

The natural frequency (N) varies inversely to the square root of the effective mass of the system (M'),
FIG. 32. Diagram of capsules of Frank and of Wiggers and Dean for optical registration. *A*, longitudinal section of Wiggers' and Dean's capsule for registering the heart sounds; *B*, longitudinal section of Frank's capsule for optical registration; *C*, end view of Frank's segment capsule and the situation of the mirror on the membrane; 1, arc lamp; 2, photographic film; 3, receiving funnel.

and directly with the square root of the volume-elasticity coefficient of the system (E'). Therefore, the natural frequency is increased by diminishing M' (large transverse section and short length of the system, high density of the transmitting fluid) or by increasing E' (diminishing distensibility: tense membranes, nondistensible material for the manometer and connections).

Frank's and Wiggers' manometers. Frank, and later Wiggers, following the principles established by Frank, endeavored to increase the natural frequency of manometers by reducing the effective mass (M'). The instruments constructed have great efficiency and give a faithful record of pressure changes in the circulatory system. Wiggers' universal optical manometer (Fig. 33) is very practical, but to insert the wide and short cannulas into the cavities of the heart or the arteries a rather traumatic operation must be performed.

Hamilton's manometer.[2] Hamilton and others have tried to increase the natural frequency by increasing the value of E' in Frank's law. A tensely drawn membrane of a very slightly distensible material allows the increase of the effective mass without diminishing the natural frequency. In this way smaller cannulas, even hypodermic needles, can be used together with a more or less long connecting system, which must be of nondistensible material, such as lead tubes. The decrease in sensitivity caused by increasing the tension of the membrane (beryllium membranes are used in current models) is compensated by lengthening the beam of light (increasing the distance between the manometer and photokymograph), a circumstance that requires a stronger source of light. A diagram of Hamilton's manometer is also given in Fig. 33. This instrument permits the recording of pressure variations in human arteries. It may also be used in connection with a catheter introduced into the heart chambers.

Gauer's manometer. When pressure pulses are registered with an intracardiac catheter, the effective mass is increased by the fluid column that fills the catheter. This diminishes the efficiency of the manometer, and the models mentioned above do not give satistactory results. Gauer and Gienapp[1] have designed a very small manometer, 2 cm. long by 3 mm. in diameter, which is easily adapted to the internal (intracardiac) end of the catheter. A diagram of this manometer is given in Fig. 34. Intracardiac pressure exerts its effect on a piston *A* against a spring *C*. Displacement of the piston makes its end (of soft iron) act on the coils of a differential transformer contained in the small compartments *D*. Cables from this transformer (not represented in the diagram) connect it through an amplifier with a recording galvanometer. A thin rubber diaphragm *B*, maintained in its place by a ring, prevents blood from entering into the system. The natural frequency of the manometer is 1,000 c.p.s. and it has a linear response from −50 to +250 mm. Hg. It can be easily calibrated with a mercury manometer by applying suction to the external end of the catheter, without having to remove it from the heart. Excellent records can be obtained with this instrument.[2]

Piezoelectric instruments. Recently instruments have come into use in which variations in pressure are converted into variations in an electric circuit (piezoelectric systems; πίεσις, pressure), which can

be registered by appropriate galvanometers. Some of them consist in a Wheatstone bridge,[1] which varies in resistance.

As yet there is not sufficient experience to judge the efficiency and usefulness of these systems. Instruments most commonly in use are manufactured by the Statham Laboratories, Los Angeles, Calif., and by the Sanborn Company, Boston, Mass.

INTRAVENTRICULAR PRESSURE CHANGES

The following analysis of the pressure pulses in the cavities of the heart is based on curves free of artefacts obtained by means of high-efficiency manometers. Intraventricular pressure should be recorded simultaneously with some other manifestation of cardiac activity, so as to have points of reference for the interpretation of the facts observed. Figure 35 reproduces intraventricular and aortic pressure records simultaneously obtained in a dog with Wiggers' optical manometers. The upper tracing corresponds to the aorta and the lower one to the left ventricle; the vertical lines in the lowest part of the record are separated by intervals of 0.04 sec.

Ventricular systole. Ventricular contraction begins at *L*. The pressure rises relatively slowly and at increasing speed up to *M*, whence it rises in a thin, almost straight line up to *N*. This point corresponds to the opening of the semilunar valves, as is shown by the fact that aortic pressure begins to rise precisely at this moment. From this moment onward, ventricle and aorta form one common cavity and the pressure changes portrayed by both curves are identical. The curves are more or less rounded, peaked, or flattened, according to the way pressure varies and according to the speed of the photokymograph. At *R* the semilunar valves close, and the ventricular pressure falls rapidly down to *S*, from which point onward it falls more gradually until it reaches the initial level.

[1] Lambert, E. H., and E. H. Wood, *Proc. Soc. Exper. Biol. & Med.*, **64**, 186, 1947; Motley, H. L., A. Cournand, L. Werko, D. Dresdale, A. Himmelstein, and W. R. Dickinson, Jr., *Proc. Soc. Exper. Biol. & Med.*, **64**, 241, 1947.

The ventricular pressure curve seldom falls below the initial level (negative pressure). A small rise *KL* is sometimes observed just before the ventricular systolic rise; it is due to the slight increase in pressure caused by the auricular systole.

Isometric contraction. The first part of the curve (*LN*) corresponds to the isometric contraction; the energy set free is entirely used to increase the tension of the heart fibers and the pressure in the ventricle, without causing any shortening of the fibers (some energy, of course, is lost as heat). Ventricular volume records show no change in size during this period; hence the term "isometric" (see page 97). As the A-V and semilunar valves are closed, blood does not enter or leave the ventricle.

At first the pressure increases gradually (*LM*) and then at greater speed (*MN*); it is usually accepted that this is due to the fact that, as excitation spreads through the myocardium, the heart fibers enter successively into contraction (*entrant contraction subphase*), and later when all the fibers are excited they are all contracted (*massive contraction subphase*).

Ejection phase. When ventricular pressure reaches the level of the aortic pressure and rises above it, the semilunar valves are opened and the mechanical conditions of ventricular contraction are altered. Energy of contraction is now used to eject the blood from the ventricle into the arteries (*ejection phase*). The heart performs "work," in the mechanical sense of the term. Immediately after the semilunar valves open (*NO*) most of the contraction energy is used to overcome the resistance of the column of blood in the aorta, and very little in moving this column (*minimal ejection subphase*). Between *O* and *P* ejection is at a maximum, and then again diminishes down to the end of systole *Q* (*reduced ejection subphase*).

Ventricular diastole. The segment *QR* corresponds to what is called the aortic incisura, or protodiastolic phase; at *R* the semilunar valves close.

From *R* onward the semilunar and A-V valves remain closed. The contents of the ventricle cannot vary, so ventricular relaxation is not accompanied by any change in the length of the fibers (*isometric relaxation*). The A-V valves open at *S* and blood flows into the ventricles. The subphases of ventricular diastole are not portrayed in the ventricular pressure curve; they can be seen in the auricular pressure, jugular pulse, and ventricular volume curves.

Right ventricle. Pressure changes in the right ventricle are essentially the same as those in the left ventricle; details similar to those described above are found in the right ventricular
FIG. 35. Intraventricular pressure (lower record) and aortic pressure (upper record) curves. Time in 0.04 sec. *K-L*, auricular wave or presystole; *L-N*, isometric contraction; *L-M*, entrant contraction; *M-N*, massive contraction; *N-O*, minimum ejection; *O-P*, maximum ejection; *P-Q*, reduced ejection; *Q-R*, protodiastole; *R-S*, isometric relaxation. From the opening (*N*) to the closure (*R*) of the semilunar valves the intraventricular and aortic pressure changes correspond perfectly.

pressure curve. The only difference is that the right ventricle has a lower maximum pressure, corresponding to the thinner wall and less developed musculature of this ventricle. Simultaneous records of right and left ventricular pressures (Fig. 36), besides the difference in amplitude, show that the rise in pressure in the right ventricle precedes by a very short time the rise in the left ventricle. This very slight asynchronism is not constant and is never greater than a few milliseconds.

Chauveau's and Marey's curves, obtained in the horse (Fig. 31), differed in several respects from the curves obtained with optical manometers in dogs. Curves obtained with optical manometers in horses,[1] however, do not differ essentially from those of the dog obtained with the same method.

[1] HOUSSAY, B. A., O. ORÍAS, and L. GIUSTI, *Rev. Soc. argent. de biol.*, **12**, 259, 1936; *J. de physiol. et de path. gén.*, **34**, 1125, 1936.

Intraventricular pressure in man. Intraventricular pressure can be recorded in human beings by introducing a catheter through a vein in the arm into the right ventricle and connecting the catheter with a suitable manometer, *e.g.*, Hamilton's.[1] The curves do not differ significantly from those obtained in animals, but as there is a long column of fluid in the catheter, artefacts are frequently recorded. Right and left intraventricular curves have been obtained in man by direct transthoracic puncture.[2] The curves are similar to those of dogs, but the procedure is, of course, an exceptional one.

Left ventricle

Right ventricle
Fig. 36. Simultaneous records of left (upper tracing) and right (lower tracing) intraventricular pressure curves. Both manometers had the same sensitivity; the difference in amplitude is due to real differences in the pressures in the right and left ventricles.

INTRA-AURICULAR PRESSURE CHANGES

The pressure in the auricles is much lower than in the ventricles or the aorta; therefore the manometers used should be more sensitive than those used for registering ventricular or aortic pressures. With the sensitiveness of the membrane thus increased, it becomes almost impossible to avoid the recording of other phenomena of cardiac activity, such as the heart sounds that are superimposed on the pressure curve.

The pressure curve of the left auricle of a dog (essentially the same as the right auricular pressure curve) is reproduced in Fig. 37. It has been obtained simultaneously with a left intraventricular pressure curve by means of Wiggers' optical manometers.

Auricular systole (presystole) produces a more or less rounded wave (Fig. 37, 1). Coincident with the isometric contraction of the ventricle there is a sharp rise in auricular pressure (Fig. 37, 2), probably due to the closure of the A-V valves, and a series of vibrations which correspond to the first heart sound. When the ejection phase begins, intra-auricular pressure drops suddenly, because the shortening of the ventricular fibers, as blood is ejected into the arteries, produces mainly a lowering of the base of the ventricles, while the apex remains almost stationary. This fall in intra-auricular pressure produces a slight suction of blood from the veins. Therefore while the ventricle is pumping out blood into the arteries, the auricle is sucking it in from the veins. The ejection impulse, however, is much greater than the sucking effect; the latter has little or no functional significance, while the pumping out of blood from the ventricle is the most important fact of cardiac activity in circulatory dynamics.

1 2 3 4
Fig. 37. Left intra-auricular (above) and intraventricular pressures registered by Wiggers' optical manometers. Time in 0.02 sec. 1, auricular systole; 2, isometric contraction and ejection phases; 3, isometric relaxation; 4, rapid inflow. The rise at the commencement of isometric contraction in the auricular pressure curve corresponds to the closure of the A-V valves.

During the reduced ejection phase there is a gradual increase in intra-auricular pressure,

[1] Cournand, A., *Bull. New York Acad. Med.*, **23**, 27, 1947.

[2] Buchbinder, W. C., and L. N. Katz, *Proc. Soc. Exper. Biol. & Med.*, **71**, 673, 1949.

which continues and becomes even more marked during the isometric relaxation of the ventricle (Fig. 37, 3). This rise in pressure is due to the continuous arrival of blood from the veins, blood that cannot pass into the ventricle because the A-V valves are closed. When these valves open, at the end of the isometric relaxation, blood flows into the ventricles and the pressure in the auricle falls (Fig. 37, 3-4). A wave is thus produced, the ascending limb of which is due to the accumulation of blood in the auricle (stasis) and the descending limb to its evacuation into the ventricle (rapid inflow phase). The summit of this wave corresponds to the opening of the A-V valves. After the ventricle has been almost completely filled, blood coming from the veins accumulates in the auricles, and the intra-auricular pressure rises (retarded inflow) up to the end of the cycle.

These changes in intra-auricular pressure are the main cause of the venous pulse, which will be studied later.

THE FUNCTIONING OF THE VALVES

The heart valves are membranes, made up of elastic connective tissue, which serve to direct the blood stream flowing through the heart. The movements of these valves are completely passive; they are caused by differences in the pressures of the cavities which they separate. They close the orifices on which they are inserted, and in normal conditions their efficiency is perfect. The auriculoventricular (A-V) valves (mitral valves on the left, and tricuspid valves on the right side of the heart) are opened when the pressure is greater in the auricles than in the ventricles and are closed when intraventricular pressure rises above that in the auricle. The semilunar valves in the aorta and pulmonary artery open when intra-ventricular pressure is higher than the corresponding arterial pressure, and close when the arterial pressure is the higher.

During the greater part of ventricular diastole, *i.e.*, from the end of isometric relaxation, throughout the auricular systole up to the beginning of ventricular systole, the A-V valves are open and blood flows into the ventricles. During this interval the semilunar valves remain closed. When ventricular systole commences, the A-V valves are suddenly closed, and a brief period elapses before the semilunar valves are opened (isometric contraction). During the ejection phase the semilunar valves are open while the A-V valves remain closed. The semilunar valves are closed in the protodiastolic phase, before the A-V valves open, so that during the isometric relaxation all the valves are closed.

The papillary muscles and the chordae tendineae, which arise from these muscles and are inserted on the free edges of the A-V valves, prevent the inversion of the valves when they close. The semilunar valves are disposed in a different way and close a smaller orifice, so they are not inverted in spite of not having any retaining fibers.

Inflammatory processes and congenital malformations can cause alterations in the valves, which disturb their function. The valves can thus narrow the orifices (valvular stenosis) or become incompetent (valvular insufficiency). In the first case, they hinder the passage of blood; in the second, part of the blood flows backward into the chamber from which it has been ejected. If these disturbances are very severe, they may be incompatible with life.

CHAPTER 14

The Heart Sounds

The activity of the heart produces certain sounds of low intensity, which can be heard by placing the ear directly on the chest wall, in the neighborhood of the heart, or by using a stethoscope for the same purpose.

Harvey, in his famous book on the movements of the heart and blood, mentioned the heart sounds, but Laënnec was the first to study these sounds and to point out the value they and their modifications had in medical practice. In 1819 Laënnec published a classic treatise on auscultation.[1]

Fig. 38. Stethoscopes.

The heart sounds are due to the vibrations that the activity of the heart causes in the heart itself or in neighboring structures. An untrained ear is not in a condition to explore the heart sounds profitably. The ear must be patiently trained, by methodic and prolonged practice; this training is a fundamental part of medical education.

Stethoscopes and phonendoscopes (Fig. 38) are used to aid the ear, especially in the localization of the sounds, and to reinforce them.

THE NORMAL HEART SOUNDS

In the course of the heart cycle at least two sounds are heard in all subjects. These stand out clearly above all others, and until recently they were the only ones generally recognized. Because of the order of their occurrence in the heart cycle, they have been called the first and second sounds. There is a short silence between them, and between the second sound of one cycle and the first sound of the following cycle there is a longer silent interval.

The first sound commences at the same time as the ventricular systole; it is described as being the lower in pitch of the two, the softer in quality, and the more prolonged. It lasts throughout the isometric phase and part of the ejection phase of ventricular systole. The second sound, which occurs practically at the end of the systole, is said to be sharper, shorter, and of a higher pitch than the first.

In a certain number of perfectly healthy subjects a well-trained ear can hear, immediately after the second, the so-called "physiologic third sound." Attention was clearly drawn to it for the first time by Gibson[1] in 1907.

Furthermore, in some normal subjects a very weak sound may be heard immediately before the first sound; it therefore precedes the ventricular systole. This sound is of such low intensity that it will not be perceived unless special care is taken to recognize it. The third sound and this other sound, the significance of which will

[1] Laënnec, T. H., "De l'auscultation médiate," Bosson et Chaudé, Paris, 1819.

[1] Gibson, A. G., *Lancet*, **2**, 1 and 380, 1907.

be examined later, frequently pass unnoticed on direct auscultation, especially if the observer ignores the possibility of their existence, but they are clearly marked in graphic records made with instruments of adequate sensitivity (Fig. 39).

The cause of the heart sounds. There are therefore four sounds per beat when the heart is contracting normally. Two of them are easily recognized; they are louder and more important than the other two, which are weaker and may not be noticed unless special care is taken during auscultation.

A detailed discussion of all the opinions as to the cause of the heart sounds would take up much space and would not be very profitable. Therefore only those which have a more solid foundation will be briefly considered. More details can be obtained in the monograph by Orías and Braun Menéndez.[1]

The first heart sound is due to four principal factors: (*a*) muscular contraction and tension of the walls of the ventricles (muscular factor); (*b*) closure of the A-V valves (valvular factor); (*c*) distention of the aorta and pulmonary artery at the beginning of the ejection phase (vascular factor); (*d*) residual vibrations due to auricular systole (auricular factor). The most important are undoubtedly the valvular and vascular factors. The others merely contribute to modify the fundamental character of the sound.

The second heart sound is due to the closure of the aortic and pulmonary semilunar valves. Therefore it takes place at the beginning and during the initial moments of isometric relaxation.

The third physiologic heart sound coincides with the end of the rapid filling phase, as has been demonstrated by the use of graphic registration. The moment of the cardiac cycle at which it occurs supports the theory that attributes it to vibrations of the ventricular wall, caused by the sudden distention produced by the rapid entrance of blood accumulated in the auricles and veins during the time the A-V valves are closed. Other theories as to the cause of the third sound are not supported by valid arguments.

The physiologic auricular sound is probably due to vibrations of (*a*) the auricular walls; (*b*) the A-V valves; (*c*) the ventricular walls distended by the auricular systole. Graphic registration has shown that vibrations originated in the course of auricular systole last longer than this systole, and the final oscillations are added to those of the first sound.

[1] ORÍAS, O., and E. BRAUN MENÉNDEZ, "The Heart Sounds," Oxford, New York, 1939.

Auscultation areas. The first heart sound is best heard over the lower part of the anterior chest wall. The clinical exploration of this sound gives valuable information on the functioning of the A-V valves, as closure of these valves is one of the main factors which produce it. The mitral valve is explored by auscultation over the apex of the heart (mitral area) and the tricusp over the base of the xifoid of the sternum (tricuspid area).
FIG. 39. The four normal heart sounds. Phlebogram, phonocardiogram, and time in 0.2 sec. The auricular sound *A* begins about 0.04 sec. after the commencement of the *a* wave of the venous pulse. The third sound coincides with the lower third of the descending limb of the *v* wave (end of rapid filling).

The second sound is best heard over the upper part of the anterior chest wall, and it gives information on the functioning of the semilunar valves. The aortic valves are explored by auscultation over the second right intercostal space, close to the sternum (aortic area), and the pulmonary valves over the second left intercostal space near the sternum (pulmonary area).

Graphic registration of the heart sounds. Phonocardiography. The vibrations which constitute the heart sounds can be registered graphically. The record obtained is called a phonocardiogram; it allows detailed analysis of the sounds, the moment in the heart cycle in which they occur, their duration, their number, and the amplitude and frequency of the vibrations.[1] The phonocardiogram is a valuable and permanent record.

Graphic registration of the heart sounds is based on the following general principle: the vibrations that would act on the tympanic membrane of the ear are made to act on an adequate resonator, the movements of which can be registered either directly, by transmitting them to a registering lever or to a beam of light, or indirectly, by making them modify an electric circuit, the oscillations of which are registered by a galvanometer. There are therefore two types of methods: (*a*) the direct or purely mechanical; (*b*) the indirect or electric.

Improvements in microphones, amplifiers, and recording galvanometers have greatly contributed to the advancement of electric phonocardiography. The records can be "picked up" by a photoelectric cell and again transformed into sound by ear receivers or loud-speakers.

[1] Phonocardiographs can omit, deliberately or otherwise, the registration of vibrations of certain frequencies.

Whatever the method used, it is convenient to register at the same time as the phonocardiogram, and on the same film, some other aspect of the heart's activity to have points of reference for the correct localization and recognition of the sounds. The venous pulse, the central arterial pulse, and the apex beat are especially useful for such a purpose. If an electrocardiogram is also simultaneously recorded, a complete picture of the heart's activity is obtained, but the electrocardiogram alone is inadequate as a reference record because it is silent during the greater part of ventricular diastole.
FIG. 40. Components of the first sound. Phlebogram, phonocardiogram, electrocardiogram, and time in 0.2 sec. The first sound is made up of two sets of vibrations, 1 and 1'. The vertical dotted line passing between the two components crosses the venous pulse record at the foot of the ascending limb of the *c* wave, *i.e.*, the beginning of the ejection phase. The first component (1) coincides with isometric contraction and the second group (1') with the beginning of ejection.

The normal phonocardiogram. The *first sound* is usually recorded as a single group of rapid vibrations, which quickly reach a maximum and then rapidly decrease (Fig. 39, 1). If the sounds are captured over the apex, the first sound is the most intense one; *i.e.*, the amplitude of the vibrations is greatest. It lasts 0.10 to 0.17 sec., and the oscillations have a frequency of 25 to 50 per second. The beginning of the first sound coincides exactly with the beginning of ventricular systole, but sometimes this is difficult to detect because the oscillations of the physiologic auricular sound fuse with those of the first sound.

Careful examination of a large number of phonocardiograms of healthy subjects, obtained from the different auscultation areas, shows that in the major-

ity of cases the first sound consists of two definite groups of vibrations separated by a very brief aperiodic interval (Fig. 40, 1 and 1′). The first group corresponds to the isometric contraction, and may therefore be called the isometric component of the first sound; the second group corresponds to the beginning of the ejection phase, and may therefore be called the ejection component. Each one of the groups has two parts, more or less clearly marked. The first vibrations (one or two) of the isometric component have less amplitude, and their frequency is lower. Probably this is due to the modifying influences of the final vibrations caused by auricular systole and to the cardiac impulse on the chest wall at the beginning of ventricular systole. The last part of the ejection component is easily differentiated, probably because of the changes caused in the sound by the acceleration of the blood stream during the maximum ejection phase.[1]

When the separation between the isometric and ejection components is more marked (*e.g.*, owing to respiratory conditions), there is a split first sound. Sometimes the auricular sound can produce a sensation on the ear that simulates a splitting of the first sound.

The *second sound* is recorded as a group of four to six ample vibrations, of frequency slightly greater than that of the first sound (Fig. 39, 2). Its duration is 0.10 to 0.14 sec. If the vibrations have been captured on the upper part of the thorax, those of the second sound are usually the ones with greatest amplitude.
FIG. 41. Reduplication (splitting) of the second sound. Phlebogram, phonocardiogram, electrocardiogram, and time in 0.2 sec. The second sound is made up of two groups of vibrations, 2 and 2′. The second group of vibrations begins before the summit of the *v* wave. Reduplication of the second sound is usually attributed to asynchronous closure of the aortic and pulmonary semilunar valves.

The beginning of the second sound coincides with the bottom of the incisura of the aortic or central arterial pulse. In optical records of the venous pulse, the second sound is always marked by several sharp oscillations or at least a notch on some part of the ascending limb of the *v* wave. Usually, but not always, the second sound coincides with the end of the T wave in the electrocardiogram (Figs. 40 and 41).

Sometimes, even in normal subjects, the second sound appears in the phonocardiogram as two groups of vibrations more or less clearly separated from each other (Fig. 41, 2 and 2′). Each of the components lasts a shorter time than that corresponding to the usual single second sound, and one component follows immediately after the other. This is known as "splitting" or "reduplication" of the second sound. Its main distinctive feature in the phonocardiogram is that the second component of the split sound is registered before the summit of the *v* wave of the phlebogram obtained simultaneously (Fig. 41).

[1] CAEIRO, A., and O. ORÍAS, *Rev. argent. de cardiol.*, 4, 71, 1937.

Splitting of the second sound is usually attributed to asynchronous closure of the semilunar valves of the aorta and pulmonary arteries. Phonocardiograms show that splitting of the second sound is less frequent than it appears to be on auscultation, because the ear easily mistakes the third sound for splitting of the second sound. The only way of arriving at a definite conclusion is to make a simultaneous record of the heart sounds and the phlebogram, or the apex beat.

The *third physiologic heart* sound is recorded more often in phonocardiograms as the sensitivity of the instruments increases. The apex and mesocardiac areas are the most favorable for registering it. In young adults with a thin chest wall it is more frequently registered than in children or middle-aged adults. It is marked in the phonocardiogram by one to six vibrations, or even more (Figs. 39 and 40). Its salient characteristic is the moment in the cardiac cycle at which it occurs. It always coincides with the final portion of the rapid ventricular filling phase, and comes half or two-thirds of the way down the descending limb of the *v* wave of the phlebogram (Figs. 39 and 40) recorded simultaneously.

The interval between the beginnings of the second and third sounds marks the delay with which the ventricle fills after the closure of the semilunar valves, *i.e.*, the duration of the isometric relaxation and rapid filling phases. In normal subjects these phases have an aggregate and very constant duration of 0.11 to 0.14 sec.
FIG. 42. Phonocardiogram in partial A-V block. Phlebogram, phonocardiogram, electrocardiogram (lead II), and time in 0.2 sec. The phlebogram and ECG show the existence of partial A-V block of the 2:1 type. The phonocardiogram shows two groups of vibrations, α and α', connected with auricular contraction. (Compare with Fig. 72.)

The intensity of the third sound varies in different subjects, and also in the same individual according to the respiratory phase in which it is recorded. The amplitude of its vibrations is usually less than that of the second sound. The duration varies from 0.07 to 0.10 sec.

The *physiologic auricular sound* is not always marked on the phonocardiograms. It appears as a group of vibrations of small amplitude, which precedes the first sound. It begins 0.02 to 0.04 sec. after the beginning of the *a* wave of the phlebogram (Fig. 39). It lasts 0.08 to 0.10 sec. Frequently the auricular sound is not clearly recorded, and care must be taken to recognize it (Fig. 41). In the majority of cases in which auscultation reveals a split first sound, the phonocardiogram shows an auricular sound.

If the heart sounds are recorded with an exploring catheter placed in the esophagus, the auricular sound is always found in the phonocardiogram. It begins earlier and lasts longer than in records obtained from the precordial area (Taquini, 1936).

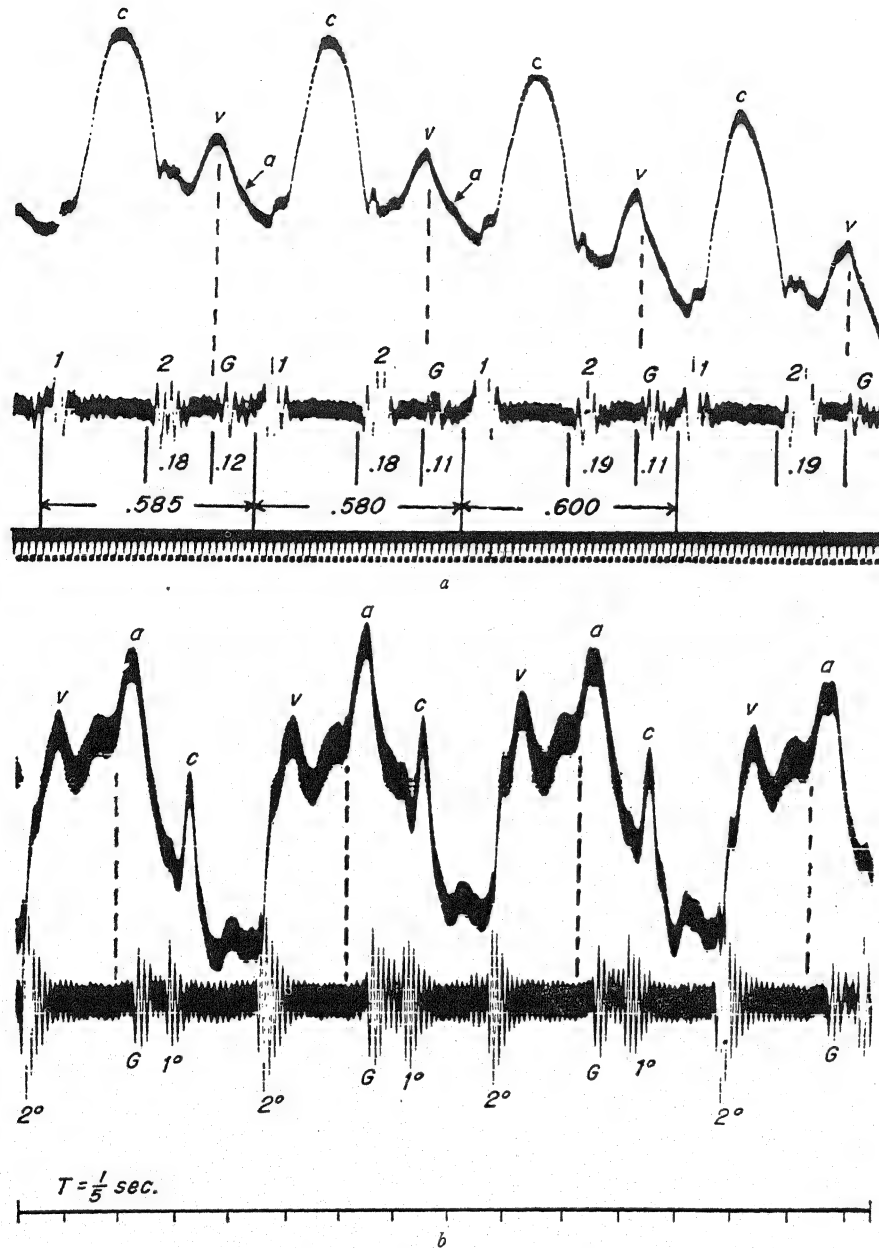
In cases of complete or partial A-V block, the


FIG. 43. Gallop rhythms. Above, records of a patient with *rapid-filling* gallop rhythm. Phlebogram, phonocardiogram, and time in 0.2 sec. The *a* wave of the venous pulse appears as a change in gradient in the descending limb of *v*, which is well marked. The *c* wave is very large ("arterialized" phlebogram). The phonocardiogram shows the first (1) and second (2) heart sounds and a third sound (*G*) which is coincident with the descending limb of *v*, and which reaches its maximum intensity before auricular systole (*a*). This rhythm might be mistaken for a presystolic gallop, as it begins nearer the commencement of the following first sound (0.11 to 0.12 sec.) than the end of the preceding second sound (0.18 to 0.19 sec). The simultaneously recorded phlebogram removes all doubt as to its being a rapid-filling gallop rhythm.

Below, phlebogram, phonocardiogram, and time in 0.2 sec. The phonocardiogram shows the first (1°) and second (2°) heart sounds and a third sound *G*. The third sound coincides with the *a* wave in the phlebogram, *i.e.*, auricular systole; it is, therefore, a *presystolic gallop rhythm.* In this case there is also a very slight delay in A-V conduction, but this is not a necessary condition for the existence of this type of gallop rhythm.

auricular sound is registered as two definite groups of vibrations (Fig. 42).

Sometimes extraneous, extracardiac sounds are registered in the phonocardiogram. The different frequency of the vibrations, the irregularity in their occurrence, and the absence of a definite relation to any event in the cardiac cycle easily permit their classification as extraneous sounds.
FIG. 44. Records of a patient with complete and incomplete summation gallop rhythms. From above down: duration of each cardiac cycle, phonocardiogram, phlebogram, and time in 0.2 sec. In cycles *A* and *B*, beside the first and second heart sounds, there are two added sounds (*G* and *G'*) very close together, but clearly different from each other. *G* coincides with the descending limb of the *v* wave in the venous pulse (rapid inflow) and *G'* with the *a* wave (auricular systole). Cycle *C* is shorter, because of respiratory arrhythmia, and the end of rapid inflow coincides with the auricular systole; therefore *G* and *G'* have been summated. This is a case of summation gallop rhythm, incomplete in cycles *A* and *B*, and complete in cycle *C*.

THE HEART SOUNDS IN SOME ABNORMAL CONDITIONS

As an introduction to the physiopathology of heart sounds, which has great importance in medical practice, the disturbances produced in a few pathologic conditions will be examined in the following paragraphs.

Gallop rhythms. According to Potain's definition, a gallop rhythm is a triple heart sound made up by the addition of a third component to the two sounds usually heard. The added sound is placed between the two others and is clearly distinguishable from them. The peculiar cadence made Bouillaud give it the name of gallop rhythm.

Phonocardiographic studies have shown that the added sound is always produced at definite moments of the cardiac cycle. Sometimes it coincides with the end of the rapid filling, *i.e.*, with the moment of occurrence of the third physiologic sound (Fig. 43). In other cases it coincides with auricular systole, *i.e.*, with the moment of occurrence of the physiologic auricular sound (Fig. 43). Finally, in the majority of cases it coincides with both the end of rapid filling and the auricular systole, which take place almost at the same time or even simultaneously because of the shortening of diastole as a result of tachycardia. In this last case two different circumstances are summated, each one of which is capable of producing on its own a third sound responsible for the gallop rhythm. Sometimes summation is not complete, and a very brief interval between the two sounds can be seen in the records (Fig. 44, cycles *A* and *B*); at others there is complete summation, and a single sound results which has an intensity greater than that of its components (Fig. 44, cycle *C*).

The added sound in the gallop rhythm is therefore only an exaggeration of normal acoustic phenomena, which occur in the course of cardiac activity and which usually pass unnoticed on auscultation. Clinical experience shows that this exaggeration occurs when there are serious disturbances in the myocardium which cause ventricular hypotonicity (hyperdistensibility). In all cases analyzed so far, the extra sound occurred in diastole, and according to the mechanism of its production, the following types of gallop rhythm can be distinguished: *presystolic gallop*, *end-of-rapid-filling gallop*, and *summation gallop*. Summation can be either complete or incomplete (Figs. 43 and 44).

A systolic gallop rhythm occurs when the added sound is interposed between the first and second normal sounds, during ventricular systole. The added sound has been attributed to the vibrations caused by the sudden distention of a fibrous cord or membrane.

Valvular opening snaps. Normally the opening of the A-V valves is a silent event, but when the valvular orifice is narrowed by pathologic processes such as adhesions or fibrous cords, the opening of the valve at the end of diastolic relaxation is hindered and the

valve becomes suddenly distended, giving rise to a peculiar snapping sound. This occurs in cases of mitral stenosis, a frequent result of rheumatic cardiac disease.

In such cases a third sound appears in the phonocardiogram, the beginning of which coincides with the summit of the *v* wave of the phlebogram simultaneously recorded. The summit of the *v* wave is due to the opening of the A-V valves; so the name "opening snap of the mitral valve" is the appropriate one for this sound (Fig. 45).

A diagram of the different possibilities of normal and abnormal heart sounds in relation to the waves of the venous pulse is given in Fig. 46.

Fig. 45. Opening snap of the mitral valve. Phlebogram, phonocardiogram, electrocardiogram, and time in 0.2 sec. Records of a case of mitral stenosis. The sound *Sn* which follows the second heart sound begins coincidentally with the summit of the *v* wave; therefore it corresponds to the opening of the A-V valves.
Fig. 46. Diagram of phlebogram and heart sounds, showing the time relations between the waves in the venous pulse and the principal types of normal and pathologic heart sounds.

Cardiac murmurs. When the flow of blood becomes turbulent (with the formation of eddies) within the heart and the velocity of the flow is greater than a certain critical speed, the ear perceives a peculiar sound called a murmur. These conditions occur in the heart when the blood flows through narrowed valvular orifices or flows back through an incompetent valve (valvular stenosis or valvular insufficiency). Murmurs are not always well recorded in the phonocardiogram.

A murmur does not always mean a valvular lesion. If the velocity of flow is increased, as in hyperthyroidism, murmurs may be heard in the absence

of valvular lesions. In cases of severe anemia, murmurs occur because the flow easily becomes turbulent, owing to the low viscosity of the blood.

CHAPTER 15

The Electrical Changes during Cardiac Activity

THE ACTIVITY OF the heart muscle is accompanied by electrical phenomena, similar in nature to those which take place when any tissue becomes active. There is still much to be learned about the intimate nature and the mechanism of these electrical phenomena.

The use of instruments easily handled and sufficiently faithful to record them, however, has greatly advanced our knowledge of this particular aspect of the heart action, in both normal and pathologic conditions. No medical examination of the heart is now considered complete if its electrical changes have not been recorded.

The electrical phenomena of the heart were discovered by Kölliker and Müller in 1856.[1] They observed that when the sciatic nerve of a frog was placed on a beating heart of the same or another animal, at each systole the muscles innervated by the sciatic contracted. They attributed the stimulation of the nerve to an electric current originated by the activity of the heart. This fundamental experiment can be repeated in the dog. The thorax is opened in an anesthetized animal kept alive by artificial respiration, and the phrenic nerve is dissected and cut. The diaphragm on the corresponding side will contract synchronously with the heartbeat whenever the peripheral end of the cut nerve is placed on the heart.

Waller[2] was the first to obtain a graphic record of the action current of the normal heartbeat, by means of Lipmann's capillary electrometer, but the first important advance in the study of the electrical phenomena of the heart took place in 1903, when Einthoven, then professor of physiology of Leyden, adapted the string galvanometer for the registration of the action currents of the heart and subsequently developed the fundamental theory of electrocardiography. The clinical and experimental studies of Lewis, Wiggers, F. N. Wilson, and others have contributed to enlarge and consolidate the basic knowledge necessary to interpret the electrical variations inherent in cardiac activity.

[1] KÖLLIKER, R. A., and J. MÜLLER, *Verhandl. d. physik-med. ges. Würzburg*, **6**, 530, 1856.
[2] WALLER, A., *J. Physiol.*, **8**, 231, 1887.

The action current of the heart is transmitted to the neighboring structures. It may therefore be recorded by connecting the galvanometer to convenient points of the body surface without even damaging the skin. When the action current is led off directly from the heart, the record is called an "electrogram" (Samojloff),[1] the term "electrocardiogram" (Einthoven) being used when the record is obtained indirectly by leads placed on the skin.

RECORDING APPARATUS

The changes in electrical potential originated by the heart action are of very small magnitude and occur in relatively fast succession. The instruments for recording them must therefore possess great sensitivity and rapidity of response (high natural frequency). The *string galvanometer*, as developed by Einthoven (1903), meets these requirements. It is based on the following principle: when an electric current flows through a conductor placed at right angles to a magnetic field, the conductor moves in a direction at right angles both to the magnetic field and to the direction of the current (Fig. 47).

Several models of electrocardiographs are manu-

[1] SAMOJLOFF, A., *Pflüger's Arch. f. d. ges. Physiol.*, **135**, 422, 1910.

factured based on the principle of Einthoven's string galvanometer, from which they differ only in details.

String galvanometers are not the only instruments used to record the action currents of the heart. Amplification of very weak currents by thermionic valves has made possible the use of oscillographs for
FIG. 47. Diagram of a string galvanometer. *S* and *N*, poles of an electromagnet; *C-C*, the string of the galvanometer; *C-F*, system of lenses; *E-D*, microscope; *A*, arrow indicating the direction in which the string moves when conducting a descending current. (*After T. Lewis.*)

this purpose. There are several types of oscillograph. Instruments are now made in which photographic recording has been replaced by a direct method. A stylet traces the curve in ink, or it is warmed so that it leaves a trace on special waxed paper. These instruments have the advantage that the record does not have to be developed but can be read immediately. They are quite as efficient as optical records.[1]

THE ELECTROCARDIOGRAM

An electrocardiogram is a graphic record of the action current of the heart led off from the body surface. There is an infinite number of points on the body surface from which this current can be led off and recorded. In order to obtain comparable results there is general agreement to place the electrodes on certain conventional places, described further on in the paragraph on the electrocardiographic leads. The tracings differ according to the lead used, but they all show certain features in common, so that a general description can be given.

The normal electrocardiogram shows at each cardiac cycle, in all the usual leads, three positive deflections or waves (above the basal or isoelectric line) and two negative ones (below the basal line) (Fig. 48). They are named with letters as proposed by Einthoven. The first deflection is positive, and corresponds to the spread of excitation in the auricles; it is known as the P wave (presystolic). The subsequent deflections are called by the letters following P in the alphabet: waves Q, R, S, and T. Exceptionally there is a sixth deflection U.

P, R, and T are positive waves; Q and S are negative. The amplitude of Q and S waves varies considerably, and in some leads they may be scarcely marked or completely absent.

Time intervals can be recorded in several ways. A system commonly used consists in a rotating motor of constant speed. A wheel attached to the motor carries five spokes at equal distances from each other, one of which is wider than the rest. The wheel rotates five times per second, therefore each rotation takes ⅕ (0.20) sec.; every 0.04 sec., one of the spokes interrupts the light for a very short time; the wider spoke will interrupt it for a slightly longer time. A fine vertical line will therefore appear on the developed record every 0.04 sec., and every fifth line will be a little wider than the others.

It has been conventionally decided to adjust the tension of the string in the string galvanometer, or the amplification power in the oscillographs, so that a current of 1 mv. causes a deflection of 1 cm. on the record. The manifest value of cardiac potentials can thus be judged from the amplitude of the deflections.

Description of the waves. The P wave is usually low and rounded, appearing as a wide tracing on the record, because of the relatively low speed at which it develops. It can reach 2 mm. (= 0.2 mv.) in height and lasts about 0.1 sec. (Fig. 48).

The anomalies in the shape, situation, direction, number, etc., of the P waves give important information on the functioning of the auricles. Nevertheless it is necessary to bear in mind that the P wave can vary considerably in size and contour in one or in several leads without this variation having an abnormal significance (Wiggers). Neither is there any relation be-

[1] HUNZICKER, W. J., and H. D. LEVINE, *Am. J. M. Sc.*, **218**, 37, 1949.

tween the size of the P wave and the strength of auricular contraction.

The waves Q, R, S, and T are related to ventricular activity. It is usual to consider them as forming two complexes: an initial, rapid complex (QRS), and a final slow complex (T). They are separated by a short isoelectric interval. The U wave first observed by Einthoven, and later by Hering and by Lewis, seldom appears; when visible it is more marked in lead II (right arm–left leg). Its significance is unknown. Artefacts due to an exceedingly slack string (owing to a high resistance in the subject's circuit) may be taken for U waves.

The Q wave is negative; it is never very prominent in normal subjects in any of the usual leads. It may be absent without having any pathologic significance.

The R wave is positive; it is usually the highest deflection, especially in lead II. The amplitude of R depends on the direction of the electrical axis of the heart (see further on) during the particular moment at which the initial ventricular complex is being recorded. In normal subjects it is 7 to 17 mm. (= 0.7 to 1.7 mv.).

The S wave is negative, varying in depth according to the subject and the lead, depending on the direction of the electrical axis of the heart.
FIG. 48. Normal human electrocardiogram, leads I, II, and III. PR (or PQ) interval, 0.16 sec.; QRS interval, 0.08 sec.; ST segment, isoelectric.

The tracing of the QRS complex in normal subjects is in thin, straight lines, of uniform width, and without slurring, splintering, or notches. These abnormalities denote slight variations in intraventricular conduction and are important when they appear in records taken in more than one lead. They are frequently observed, even in healthy subjects, in lead III (left arm–left leg). In this lead the initial ventricular complex is so irregular in some cases that the three waves cannot be distinguished; the complex is then said to be of vibratory type. When there are no other

anomalies, this has no pathologic significance. Figure 49 shows a record with splintering of the ascending limb of R and thickening of the summit of S.

The T wave in normal human subjects is always positive in leads I and II; but it is sometimes negative in lead III. T is a relatively slow and rounded wave; its height in lead II is approximately one-quarter to two-fifths the height of R. Anomalies in the T wave depict myocardial damage (infectious, toxic, nutritional).
Fig. 49. "Splintered" and "thickened" ventricular complex. The R wave does not have the straight, thin lines of the normal ECG, but has its ascending limb "splintered." The deep S wave has a thickened summit.

Time relations. Certain time relations in the electrocardiogram are of great importance. The interval between the beginning of P and the beginning of Q (R, when Q is missing), known as the PQ, or PR interval, lasts from 0.13 to 0.18 sec.; its variations indicate abnormalities in the time relations between the auricular and ventricular contractions. An interval of more than 0.18 sec. denotes a delay in conduction from the auricles to the ventricles—a first degree of auriculoventricular block.

The QRS complex in normal subjects never lasts more than 0.10 sec.; its duration is usually from 0.06 to 0.08 sec. The duration of QRS is prolonged in cases in which excitation spreads by abnormal routes and one ventricle is stimulated before the other; this occurs in cases of ventricular extrasystoles, or when there is a block in one of the branches of the His bundle (bundle-branch block). In these cases T is usually enlarged and of opposite direction to the QRS complex (Fig. 50).

The total duration of QRST—known as the *electrical systole*—is approximately the same as that of the mechanical systole, but it cannot be used to determine the duration of the contraction of the heart.

The interval between the initial and final ventricular complexes, known as the ST interval, is particularly significant. In normal conditions its duration varies with the shape and size of T, but it is always isoelectric, *i.e.*, the record should be at the same level as during diastole, or not more than 1 mm. above or below this level. A greater deviation indicates anoxia in the myocardium (asphyxia, coronary occlusion, compression of the coronary arteries by pericardial effusion).

Mechanical events and the electrocardiogram. The deflections of the electrocardiogram precede all mechanical events in the activity of the heart to which they are connected. Figure 51 shows that the beginning of the systolic rise in intraventricular pressure occurs when the ascending limb of the R wave of the simultaneously recorded electrocardiogram (lead II) has been completed. The increase in intraauricular pressure also begins when the P wave of the electrocardiogram has reached its summit. Usually the beginning of the electrical deflection precedes the beginning of the mechanical event by 0.01 to 0.03 sec.
Fig. 50. Ventricular premature beats (X) provoked by direct electrical stimulation of the right ventricle in the dog. The premature beats appear in advance of the normal beat, the QRS complex is lengthened, and there is a large T wave in the opposite direction to the initial complex (lead II).

There is a certain degree of coincidence, by no means absolute, between the end of the T wave and the end of ventricular systole.

There is no relation whatsoever between the strength of ventricular systole and the amplitude of the electrical deflections. A vigorous systole may be accompanied by a small electrical deflection and vice versa.

Before accepting any of the current hypotheses, since none gives a complete explanation, it is best simply to describe these facts, even though they may appear to be disconnected, until further observations permit an integrated and satisfactory interpretation.
FIG. 51. Simultaneous records of mechanical changes (pressure pulses) and electrocardiogram in the dog. Aortic pressure, left intraventricular pressure, ECG (lead II). Time in 0.04 sec. The T wave is frequently negative in the dog in lead II, as in the case recorded. The first sign of ventricular activity in the intraventricular pressure pulse (*L*) corresponds to the summit of the R wave in the ECG. The end of ventricular systole in the pressure curve (*Q*) corresponds to the end of the T wave in the ECG, but this is not always so. Mechanical changes in the auricle begin at *S*, when the P wave of the ECG has ended.

THE MEANING OF ELECTROCARDIOGRAPHIC WAVES

There is as yet no unanimous agreement regarding the exact meaning of electrocardiographic deflections. There is not even agreement as to the nature of the fundamental electrical process. There are, however, several well-known but more or less isolated facts, which undoubtedly represent only partial aspects of the problem but are important for its complete solution.

Electrical variations in a single isolated myocardial fiber. When a microelectrode, connected with an adequate recording system, is inserted into a single myocardial fiber of the ventricle in the beating heart of a frog, a series of well-marked electric deflections are registered.[1] If the electrode is placed simply in contact with the outside surface of the fiber without penetrating into it, a basal isoelectric line is registered. If the needle punctures the membrane and enters

[1] WOODBURY, L. A., H. H. HECHT, and A. R. CHRISTOPHERSON, *Am. J. Physiol.*, **164**, 307, 1951; WOODBURY, L. A., and H. H. HECHT, *Circulation*, **6**, 172, 1952.

into the fiber during diastole, a sudden electrical potential appears and the galvanometer shows the passage of a direct current with the negative pole inside the fiber. This is the *membrane resting potential*. When the fiber enters into systole, this potential rapidly falls to zero; it then reverses
FIG. 52. Membrane potentials of cardiac fibers. *RP*, resting potential; *AC*, action current; *HP*, hyperpolarization following action current. Ordinate, millivolts; abscissa, time in 0.1 sec. (*After Woodbury, L. A., H. H. Hecht, and A. R. Christopherson, Am. J. Physiol., vol. 164, p. 307, 1951.*)

as the inside of the fiber becomes positive with respect to the outside (Fig. 52). This inversion of the intracellular potential is known as depolarization, and it corresponds to the activation of the myocardial fiber. A period of gradual *repolarization* or recovery follows, during which the membrane potential slowly returns to the resting state. This sequence of depolarization and repolarization is known as the "membrane action potential," to distinguish it from action potentials registered on the surface of the cell. If the microelectrode is withdrawn from the cell, whatever voltage is present disappears and the isoelectric line is again recorded. The membrane action potential lasts as long as the action potential of the whole fragment of myocardium or the heart of which the fiber forms part. The average membrane resting potential of several observations was found to be −64.5 mv., and the peak of the membrane action potential was +12.7 mv.

Electrical deflections in myocardial fragments. Since Frédéricq's[1] original observations, it is well known that small fragments of myocardium, even fragments taken from the auricles, show action potentials with a rapid and a slow component similar to the QRS and T components of the electrocardiogram respectively. Records obtained by means of bipolar electrodes placed on the heart or on a fragment of myocardium, even though they are separated by only a few millimeters and lead off action potentials arising in the small mass of underlying tissue, also show a first rapid component similar to QRS followed by a slow component similar to T.

Records taken from myocardial fragments of various shapes and from limited areas of the heart (by means of bipolar electrodes placed near each other) show that the rapid component, similar to QRS, is inverted when excitation spreads from the opposite direction to that taken in a first record. On the other hand, the slow component, similar to T, remains unaltered whatever the direction of the spread of excitation.[1] This fact is important for the interpretation of the significance of electrocardiographic waves, since it suggests that the rapid and slow components are due to two different processes, the former depending on the direction of the spread of the excitation and the latter not (dual origin of waves).

Electrocardiograms of univentricular hearts. The electrocardiograms of hearts with a single ventricle (fishes, amphibians, and some reptiles) are not very different from the electrocardiograms of hearts with two ventricles (other reptiles, birds, mammals). In all of them there is a P wave, corresponding to auricular systole, and two components, QRS and T, corresponding to the ventricular systole. In amphibians usually another small wave, corresponding to the arterial (aortic) bulb, is recorded. The QRS and T components are very similar to the homonymous deflections of mammalian hearts,[2] although slower.

Current interpretations. It is well to keep in mind that the usual interpretations of the intimate processes which give rise to the ECG are merely hypothetical, and that none of them can be considered as completely and definitely established.

According to the classic idea of the fundamental electrical phenomenon, active parts of the myocardium become electronegative with respect to inactive parts (the relative-negativity hypothesis). More recent studies, however, seem to show that a double electrical variation takes place in each active unit, *i.e.*, a negative and a

[1] FRÉDÉRICQ, H., *Arch. internat. de physiol.*, **11**, 234, 1911; **12**, 66, 1912.

[1] AMUCHASTEGUI, S. R., O. ORÍAS, and A. S. SEGURA, *Rev. Soc. argent. de biol.*, **18**, 138, 1948.

[2] LEPESCHKIN, E., "Modern Electrocardiography," Williams & Wilkins, Baltimore, 1951.

positive potential, not simply a relative negativity (the doublet or dipole hypothesis).

The ventricular complex (QRS and T) is due, according to many workers, to a band of dipoles (Fig. 53*A*) which moves along the heart as the process of excitation advances.[1] Others[2] interpret it as due to the algebraic summation of two asynchronic monophasic currents (interference theory) (Fig. 53*B*). On the other hand, Thomas Lewis, interpreting carefully taken records of the spread of excitation through the heart, concluded that the QRS component of the ventricular mammalian ECG is the result of the algebraic summation of electrical variations in each ventricle.

Much has still to be learned about the intimate processes which give rise to electrical phenomena in the heart and about why the ECG shows the deflections that are in fact recorded. Clinical observations and experimental studies have, however, given enough facts to permit the diagnosis and interpretation of many typical functional and organic disturbances in cardiac functions.

THE ELECTRICAL AXIS OF THE HEART

Definition and general idea. A vector symbolizes a magnitude with a definite direction. It is represented by an arrow, the length of which gives the strength and the point of which gives the direction of the force. Physical forces are represented by vectors. The electromotive force developed by the heart at any moment can be symbolized by a vector, figured by an arrow. This vector is called the *electrical axis of the heart*. The length of the arrow indicates the voltage or the *manifest potential* resulting from the electromotive forces developing at any given moment, and the direction of the vector indicates the sense in which the current flows.

The absolute value, *i.e.*, the total electromotive force developed by cardiac activity, cannot be determined by the ECG as it is usually recorded. The manifest potential difference is only a fraction of the actual potential difference, but it changes in direct ratio with the latter and can be established by the amplitude of the deflections recorded in two or more leads.

Fig. 53. Current interpretations of the ECG. *A*, galvanometric record (below) as the dipole (above) approaches, lies under, and recedes from the exploring electrode P. *B*, resultant electrograms of summation of two monophasic potentials 1 2 and 1′ 2′. *C*, left, theoretic curve of a record corresponding to the situation illustrated in *A*; right, tracing of a record obtained experimentally with an exploratory electrode. The electrical condition of the heart during systole can be defined as a complex system of dipoles arising more or less simultaneously in the heart, which is surrounded, without any interposing isolating layer, by conducing tissues. Physically this is the equivalent of a system of multiple charges arising in a sphere submerged in a weak conducting medium.[1] These charges can be simplified at any given moment into a resultant dipole, and can be represented by a vector in space.

Einthoven's[2] mathematical and experimental

analysis showed that it is possible to establish the electrical axis of the heart by leading off currents from different angles, because the amplitude of the deflections in the ECG varies with the inclination of the derived current. When the derived current (the line joining the two electrodes) is parallel to the electrical axis, the deflections are maximal.
FIG. 54. The electrical axis of the heart. *RA*, right arm; *LA*, left arm; *I*, lead I; *II*, lead II; *III*, lead III. The deflections caused by the action current of the heart in each lead will correspond in size to the projection of the arrow on each side of the triangle (x_1y_1; x_2y_2; x_3y_3). (*From Wiggers, C. J., "Physiology in Health and Disease," 4th ed., Lea & Febiger, Philadelphia, 1944.*)

During the electrical systole the electrical axis is continuously changing in magnitude and direction. In electrocardiographic studies the following aspects are usually considered: (*a*) the instantaneous electrical axis; (*b*) the mean electrical axis; (*c*) the ventricular gradient; and (*d*) the complete evolution of the cardiac vector during the whole cycle (vectorcardiogram).

Instantaneous electrical axis. The instantaneous electrical axis, or instantaneous cardiac vector, is the vector representing the resultant of all the electromotive forces of the heart at a given moment. Its projection on a frontal plane can be calculated from the ECG obtained by the three limb leads. Einthoven represented the three standard leads by the three sides of an equilateral triangle with the heart in the center. The electromotive forces arising in the heart at any given moment can be represented by the electromotive force of the equivalent dipole, the magnitude and direction of which can be figured by a vector symbolized by $\widehat{E}$. On each side of the triangle the amplitude of the deflection of the corresponding lead is laid on to the right or the left of the zero point according to the sign of the deflection. Perpendicular lines from these points are traced toward the center of the triangle (Fig. 54). The instantaneous axis can be calculated at any moment of cardiac activity by projecting the amplitude of the deflections in two or more leads at that moment.

Mean electrical axis. The mean electrical axis represents the average of all the instantaneous vectors corresponding to the QRS groups, or to T or P waves. Usually the mean electrical axis of QRS and T are the ones calculated, establishing the size, direction, and sign of the vectorial quantities. The electrical axis for QRS ($\hat{A}_{QRS}$) is known as the mean electrical axis of depolarization, and $\hat{A}_T$ as the mean electrical axis of repolarization, in agreement with the hypothesis that connects these deflections with the respective electrical processes.

The mean electrical axis for QRS is calculated by determining the area of the positive waves, *i.e.*, those above the isoelectric level (R wave), and subtracting the area of the negative waves, *i.e.*, those below the isoelectric level (Q and S). This *net area* of QRS is determined for the deflections of at last two leads, *e.g.*, lead I and lead II, and the figures obtained are projected on the corresponding side of the Einthoven triangle. The point where the perpendiculars meet inside the triangle gives the vector or mean electrical axis for $\hat{A}_{QRS}$ projected in the frontal plane (Figs. 55 and 56).

The electrical axis of the T wave $\hat{A}_T$ is established in a similar way by projecting on the corresponding sides of the triangle the net area of T in at least two leads. If T is biphasic, the negative area is subtracted from the positive area.

The surface covered by the deflections can be determined by means of a planimeter, after amplification of the record, if necessary. For practical purposes

sufficiently accurate results can be obtained by considering the deflections as triangles and calculating the surface by multiplying the base by half the height (amplitude).[1] The areas thus obtained and the resulting vector represent microvolts per second. Electrocardiographic paper or film commonly in use has the
FIG. 55. Einthoven's triangle and triaxial system for determining the electrical axis of the heart.

vertical lines separated by 0.04-sec. intervals and the horizontal lines at 1-mm. intervals, so that each small square corresponds to 4μ v/sec. This is known as one Ashman unit (AU), and the area of the deflections is usually given in Ashman units when calculating the mean electrical axis. Einthoven's triangle can be substituted by a triaxial system, derived from the triangle (Figs. 55 and 56).

The direction of the manifest mean axis QRS ($\hat{A}_{QRS}$) is defined by Einthoven's α angle (see next paragraph), and its magnitude in microvolts per second, *i.e.*, in Ashman units.

Variations in the electrical axis of the heart. The direction of the electrical axis is not strictly dependent on the direction of the anatomical axis of the heart. The electrical axis is also determined by the relative predominance of the ventricular masses and the path of the spread of the process of excitation along the heart.

The angle formed by $\hat{A}_{QRS}$ (mean axis of QRS) or $\hat{E}_R$ or $\hat{E}_S$ (instantaneous axis for the peaks of R or S, according to which is the predominant deflection) and the horizontal line is called the α angle. It has been conventionally established that α values begin on the left of the subject in the axis corresponding to 3 o'clock. They are considered to be positive when falling below this horizontal line, and negative above it. Bayley[1] has proposed the division of the angles into sextants of 60° each, numbering them counterclockwise beginning on the left of the patient (Fig. 55).
FIG. 56. Ventricular gradient. Vector $\hat{G}$ (the ventricular gradient) is obtained by algebraic summation of vectors $\hat{A}_{QRS}$ and $\hat{A}_T$. The divisions on the radii correspond to Ashman units.

The direction of the normal mean QRS axis varies considerably with the age of the subject. In infants less than 6 months old the axis is markedly deviated to the right (+130°). Between the first and fifth year the axis shifts toward the left; the average for these years is +52°. At puberty it again shifts to the right (+67°), and in the adult it moves to approximately +60°.

In abnormal conditions (ventricular hypertrophy, bundle-branch block, ventricular ectopic beats) the axis may show most variable directions. Table 16 gives the values of α and the net areas of QRS (considered in block as positive or negative) in leads I, II, and III, and the unipolar limb leads, for the different positions of the electrical axis.

Ventricular gradient. In normal conditions the quantity of electricity evolved in the process of excitation (depolarization phase) should be the same, though of opposite sign, as that evolved during the process of recovery (repolarization phase). The area of QRS, if these deflections

[1] ASHMAN, R., and R. H. BAYLEY, *Am. Heart J.*, **25**, 16, 1943.

are admitted as the electrocardiographic sign of depolarization, should be the same as the area of T, if this wave is considered as the sign of repolarization. The sum of the two areas should be zero, since they are of opposite sign, but it is found that this is not so; therefore, if the hypothesis is still to be considered valid, it must be admitted that the process of repolarization differs from the process of depolarization by some sort of deviation. This break, or drop, or gradient in the physiological uniformity of the heart muscle can be determined quantitatively, according to Wilson and his associates,[1] by the algebraic summation of the net areas of QRS and T. The number thus obtained is called the ventricular gradient.

Independently of the validity of the hypothesis on which it is founded, determination of the ventricular gradient has become a common procedure in electrocardiographic analysis which may allow important deductions.[1]

The ventricular gradient is, therefore, the sum of the vector quantities of QRS and T, *i.e.*, $\hat{A}_{QRS} + A_T$, determined by the procedure explained in the preceding section.[2] The resultant (or sum) of the two vector quantities is equal, in magnitude and direction, to the diagonal of the parallelogram of which they form two sides. The ventricular gradient $\hat{G}$ is determined by first establishing the mean axes of QRS and T, and then adding the vectors that represent them (Fig. 56). The frontal projection of the gradient is thus obtained. It should not be overlooked, however, that the ventricular gradient, like the vectors from which it derives,

Table 16. Classification of the Mean Electrical Axis of QRS According to Its Orientation

should really be considered in space, not simply in one plane projection.

The average manifest potential of Ĝ (size in frontal projection) is 13.0 units (1 unit = 4 μv/sec.), slightly more in males than in females, with a maximum around 23.0 and a minimum around 2.5 units. The direction varies normally between 0° and +90°. The ventricular gradient varies with the heart rate; it has a tendency to decrease as the rate increases.

Ventricular-gradient determinations are useful for interpreting the significance of T changes. If a variation in T is due simply to a modification in the anatomical position of the heart, the ventricular gradient will remain normal. If the change in T is due to a pathologic process in the myocardium, the ventricular gradient will be abnormal in both size and direction. Coronary occlusion causes typical alterations in the ventricular gradient (see Ashman, Bayley, etc.).

Vectorcardiography and Vectorcardiogram

The vectorcardiogram is the record showing the evolution in time of the representative vector of the resultant of the electromotive forces arising during the whole cardiac cycle. The vectors of each moment are determined, and their apexes are joined by a continuous line (Fig. 57). The object of vectorcardiography is to obtain vectorcardiograms in order to analyze the electrical activity of the heart.

Einthoven, Fahr, and De Waart[1] determined the instantaneous vectors in leads I, II, and III for 10 moments at equal intervals during the recording of the QRS component. Mann[2] joined the apexes of these vectors and obtained graphs which were called vectorcardiograms. The cathode-ray oscillograph (see Chapter 66) is particularly appropriate for this purpose as it gives directly and automatically the tracing which includes all the resultant vectors, moment by moment, throughout the cardiac cycle, projected on any desired plane (plane vectorcardiography), so that the vectors can be considered also in space (spatial vectorcardiography or stereovectorcardiography). Schellong[3] and Wilson and his associates[4] were the first to use the cathode-ray oscillograph for obtaining plane vectorcardiograms. Later the method has been used to analyze the vectors in space.[1]

to obtain comparable results it would be necessary to adopt a uniform technique. This, however, has not yet been achieved, and each worker or group of workers uses the method he considers most advantageous. Everyone admits, however, that stereovectorcardiography gives more complete results; therefore the records should be obtained in at least two planes—simultaneously, with two oscillographs, or successively, if there is only one oscillograph. Usually vectorcardiograms in the frontal and sagittal planes are recorded, and sometimes a third one in the horizontal plane is also obtained.

Valid results are obtained in vectorcardiography with the cathode-ray oscillograph only when both electrodes are placed at the same distance from the heart and when this distance has a certain magnitude.[1] In man, the minimum distance should be 12 cm.[2] Several leads have been proposed for obtaining spatial vectorcardiograms. Some workers consider the heart to be embedded in an approximately regular tetrahedron,[3] or in a rectangular trihedron,[4] or in the center of a cube.[5] If the tetrahedron conception is adopted, three electrodes are placed one on each arm and the left leg as for the standard ECG, and a fourth on the back immediately to the left of the mid-line at the level of the seventh dorsal spinal process (Wilson *et al.*). A frontal-plane exploration is obtained with the electrodes on the right and left arm connected to the oscillograph plates which give horizontal deflections, and with one electrode on the left leg and the other a Wilson central terminal (see page 137) connected to the plates which give vertical deflections. A sagittal-plane exploration is made when a Wilson central terminal and the dorsal electrode are connected to the plates giving horizontal deflections, and a Wilson central terminal and the electrode on the left leg are connected to the plates giving vertical deflections. Figure 58 shows the connections when two oscillographs are used.

[3] WILSON, F. N., F. D. JOHNSTON, and C. E. KOSMANN, *Am. Heart J.*, **33**, 594, 1947; CONWAY, J. P., J. A. CRONVICH, and G. E. BURCH, *Am. Heart J.*, **38**, 537, 1949.

[4] DUCHOSAL, P. W., and J. R. GROSGURIN, *Circulation*, **5**, 237, 1952.

[5] GRISHMAN, L., E. R. BORUN, and H. L. HAFFE, *Am. Heart J.*, **41**, 483, 1951.

If the rectangular-trihedron conception is adopted (Duchosal and Grosgurin), four points are marked, three on the back and one on the chest, all at the same distance from the heart (Fig. 59). The frontal plane is explored with the electrodes *OP* connected with the plates giving horizontal deflections, and the electrodes *ON* connected with the plates giving vertical deflections (Fig. 60). A horizontal transverse plane at the level of the sternal margin of the fifth or sixth intercostal space is explored when the electrodes *OP* are connected with the plates giving horizontal deflections and the electrodes *OQ* are connected with the plates giving vertical deflections.

If the cube hypothesis (Grishman *et al.*) modified by Lamb and Dimond[1] is adopted, electrodes are placed on the right and left arm, a third one on the abdomen immediately above the umbilicus, another on the back at the level of the second lumbar vertebra, and lastly one on the right midaxillary line at the same level as the two preceding electrodes (Fig. 61). A frontal vectorcardiogram is obtained when the arm electrodes are connected with the plates giving horizontal deflections and the right-arm electrode and the midaxillary-line electrode with the plates giving vertical deflections. A sagittal vectorcardiogram is obtained when the right-arm electrode and the midaxillary electrode are connected to the plates giving vertical deflections and the abdominal and lumbar electrodes are connected with the plates giving horizontal deflections. A horizontal vectorcardiogram is obtained when the right- and left-arm electrodes are connected with the plates giving horizontal deflections and the umbilical and lumbar electrodes with the plates giving vertical deflections.

The polarity of the electrodes must be taken into account on making the connections. The deflections should be calibrated, and it should be possible to recognize the direction of displacement of the luminous spot on the screen.

FIG. 61. Electrode placement for spatial vectorcardiography, according to the cube hypothesis. (*After Lamb, L. E., and E. G. Dimond, Am. Heart J., vol. 44, p. 165, 1952.*)

Vectorcardiographic loops. A deflection in the oscillographic (or galvanometric) record due

[1] LAMB and DIMOND, *loc. cit.*

to electric currents arising in the heart is caused by a difference in the potentials at the points where the electrodes are placed. A dipole is, therefore, established as the resultant of all the electrical changes that occur. As there are several deflections of different amplitude and sign in the course of the cardiac cycle, the fundamental electrical phenomenon may be resolved into several dipoles of varying intensity and direction. Each one of the waves in the ECG is the expression of a dipole. The duration and shape show in each case that the vector alters in size, direction, and sign as time passes. A cathode-ray oscillograph connected to the body, as described above, can therefore show the evolution of several vectors, each one in the shape of a loop, the figure being always a closed one.

Usually vectorcardiograms show three principal loops corresponding to the development of the processes which in the ECG give the P, QRS, and T waves (Fig. 62). The symbols for these loops are P sÊ-loop, QRS sÊ-loop, and T sÊ-loop. The *axis of the loop* is the line joining its origin with its furthest point. It corresponds to the *instantaneous electrical axis* at that moment. Visualized in space, these loops should be considered as limiting plane areas.

The components P, QRS, and T of the vectorcardiogram can be represented in space by wire models of the corresponding loops which are mounted according to the spatial relations shown by the results obtained in the different planes. Graphic reproduction of these models is obtained by stereoscopic photographs.

FIG. 62. Normal vectorcardiograms. Right, frontal-plane projection; left, sagittal-plane projection in the same subject. P, QRS, and T loops are figured. Heavy line records slow movement; broken line, rapid movement. (*After Conway et al., Am. Heart J., vol. 38, p. 537, 1949.*)

Normal vectorcardiogram.[1] There are individual variations in the vectorcardiograms of normal subjects, but certain features are common to all (Fig. 62).

The axis of the P sÊ-loop is directed downward, slightly forward, and to the left. The anterior surface of the area it encircles is directed upward and to the left. It is recorded counterclockwise when facing the subject. Its contours vary more with respiration than those of QRS sÊ and T sÊ-loops; they lengthen, narrow, and become more vertical during inspiration.

The axis of the QRS sÊ-loop is directed downward, forward, and toward the left. The loop has an elliptical shape, its width being less than one-third its length. The anterior aspect of the area it encircles is directed upward and to the right. It is recorded clockwise when facing the subject, slowly at first, then faster throughout the major portion, and slowly again near its end.

The axis of the T sÊ-loop is directed downward, forward, and to the left. The loop has a very narrow elliptic shape. The anterior aspect of the surface it encircles is directed upward and to the right. It is recorded clockwise when facing the subject, slowly in the efferent portion, faster in the afferent portion.

[1] CONWAY, CRONVICH, and BURCH, *loc. cit.*

The ratio of the axes of P sÊ-loop, QRS sÊ-loop, and T sÊ-loop is approximately 1:10:2.

The vectorcardiogram can be traced from the ECG records in several leads, and reciprocally from the spatial vectorcardiogram it is possible to deduce the shape of the ECG components in the different leads, including the precordial leads[1] (Fig. 63).

FIG. 63. Vectorcardiogram and ECG. Above: frontal and transverse vectorcardiogram (accurate copies of original tracings). Numbers along vectorcardiogram, time in 0.01 sec. The T curve is drawn more darkly than the QRS; P is not represented. Scale of amplification is indicated on perpendicular axes of the vectorcardiograph figures (0.2 mv.). The broken lines represent the actual unipolar axes V_R, V_L, V_F, and V_1 to V_6. Dotted line connecting points 1 to 6 (V_1 to V_6) reproduces part of the transverse perimeter of the thorax at the level of the ventricular mass. Below: table of comparisons between real ECG (left in each of three columns) and ECG derived from the vectorcardiogram (right in each of three columns). (*Duchosal, P. W., and J. R. Grosgurin, Circulation, vol. 5, p. 237, 1952.*)

THE ELECTROCARDIOGRAPHIC LEADS

The recording of an ECG is the equivalent of exploring, by means of a recording galvanometer, the electric field created by the activity of the heart. An electric field is established when an electric potential arises in a conducting medium. It is defined by lines of flow and equipotential planes. The lines of flow show the passage of current, *i.e.*, the paths along which electrons travel owing to the existence of different potential levels. Equipotential planes are perpendicular to the lines of flow and correspond to the different points in the field which are at the same potential level.

In the case of a dipole in a homogeneous weak conducting medium, points at the same potential form spheres. A section through a field arising in pointlike positive and negative poles placed near to each other shows isoelectric

[1] DUCHOSAL and GROSGURIN, *loc. cit.*

lines (sections of the corresponding spheres) distributed as in the diagram in Fig. 64. The lines of flow are not represented. The line *I-I* corresponds to points at zero potential due to reciprocal neutralization of charges of opposite sign. All points on the right of this line will have a certain charge; points on the left will have charges of the opposite sign. The potential (both positive and negative) will decrease as the point considered lies farther from the source until it falls to zero for points at infinity.

Electromotive forces arising during cardiac activity can be resolved at each moment into a dipole with an electric field which does not differ much from that represented in Fig. 64.The main difference would be a less regular distribution of the isoelectric lines due to differences in conductivity of the different tissues surrounding the heart and to the limitation of the conducting medium by the body surface.

If two points in the field are connected by a conductor (a metal of much lower resistance than that of the medium in which the dipole is situated), a current will flow along it if the points are at different potential levels. A galvanometer inserted in the conductor will show the passage of current and its variations, thus permitting the exploration of the electric field. A recording galvanometer gives records of current deflections which permit a more detailed analysis. By placing the ends of the conductor (electrodes) at different points, a clear idea of the electric field can be obtained.
FIG. 64. Electric field of a dipole. Distribution of isoelectric planes created by a dipole in a homogeneous unlimited tridimensional medium. S, S, axis of the dipole; I, I, plane of zero potential. Figures to the left of I, I, values for positive charges; corresponding circles to the right of I, I, have the same absolute values but of opposite sign.

There is no object in examining all the possibilities, but the current will be at a maximum when the electrodes are placed on the axis *S-S* (Fig. 64) of the dipole, since the difference in potential is highest for points on this line; there will be no passage of current if the electrodes are placed on the line *I-I* perpendicular to the axis *S-S* and passing through the center of the dipole. If the electrodes are placed on lines parallel to the axis of the dipole, a current will pass which will be greater (for a given distance between the electrodes) the nearer the line is to the axis, and will be at a maximum when the electrodes are placed directly on the poles (maximum positivity and negativity). On the contrary, there will be no passage of current if the electrodes are placed on lines perpendicular

to the axis of the dipole at points situated at the same distance from the poles because these lines join isoelectric points.

The electric field produced by electric potentials arising in the course of cardiac activity is not stationary, as was explained when discussing the electrical axis of the heart. The dipole that arises is continually changing in potential and in the direction of its axis (the line joining the poles). At times it is completely reversed; thus the dipoles corresponding to the deflections Q or S are orientated in the direction opposite to that giving rise to the R wave.

Direct leads. When the electrodes are placed directly on the surface of the heart, the derivation is called a direct lead. This is a valuable method in experimental work, but can be applied to human beings only in exceptional cases, *e.g.*, in the course of intrathoracic operations.

Indirect leads. The cardiac electric field is usually explored by placing the electrodes on the body surface (indirect leads).

Standard limb leads. Einthoven recommended certain leads which since then have come into universal usage. The electrodes are placed on the limbs, and usually three combinations are used: lead I, right arm–left arm; lead II, right arm–left leg; and lead III, left arm–left leg. These three leads give a general idea of the cardiac potentials. They have already been referred to when describing the deflections in the ECG and when the electrical axis of the heart was discussed.

Precordial leads. A more localized analysis of cardiac potentials can be made by placing one electrode on the chest in the precordial area, and the other in some distant part of the body. This way of exploring the heart by placing one electrode near the source of the potentials is similar to the semidirect exploration made by placing one electrode directly on the surface of the heart (exploring electrode). The near electrode can thus capture potentials which owing to their small magnitude cannot be registered by the distal electrode.

An indefinite number of chest leads might be used, but in order to simplify the technique and to obtain comparable results, the exploring electrode is usually placed on one of the six following points:

1. On the right sternal margin at the fourth intercostal space.
2. On the left sternal margin at the fourth intercostal space.
3. Midway between the left sternal margin and left mid-clavicular line, at the level of a line going from the anterior end of the fourth intercostal space and the apex beat.
4. On the mid-clavicular line at the level of the apex beat.
5. On the left anterior axillary line at the level of the apex beat.
6. On the left midaxillary line at the level of the apex beat.

If the distal electrode is placed on the right arm, the precordial lead is called CR; it is CL if it is placed on the left arm, and CF if it is placed on the left leg. The precordial point explored is noted by a subscript using the figures given above, *e.g.*, CR_4, CF_5, etc. The galvanometer should be connected so that a positive charge in the precordial region provokes an upward deflection in the record. This result is obtained by connecting the precordial lead to the cable used for the left arm in the instruments commonly in use.

Wilson's central terminal. Wilson has suggested the use of a common terminal connected through 5,000-ohm resistances to each one of the right-arm, left-arm, and left-leg electrodes. The leads in this case are called CV with a subscript for the precordial point explored, *e.g.*, CV_2.

The object of Wilson's central terminal is to counterbalance potentials arising in the limbs so that the potential in the conductor remains sufficiently constant to be considered as zero during any moment of the cardiac cycle. If this were so, electrocardiograms obtained by this method would register only potential changes produced under the exploring electrode and would be similar to those given by a semidirect lead. Recent studies, however, have shown that derived potentials from any part situated outside the cardiac mass, even when very close to the heart, are due to the total resultant cardiac dipole[1] and that precordial leads reflect the mean direction in space of all the cardiac potentials, without any significant dominance on the sense of the deflection by that part of the myocardium which is immediately under the electrode.[2] It has been maintained that a unipolar lead is never obtained in electrocardiography.[3]

[2] Grant, *loc. cit.; ibid.*, **2**, 676, 1950.
[3] Spang, K., *Ztschr. f. Kreislauff.*, **38**, 405, 1949.

Limb unipolar leads. Following the ideas of Wilson and his associates, the study of so-called "limb potentials" has been much in vogue. One of the poles of the galvanometer is connected successively to each one of the limbs (right arm, left arm, left leg) so that a positive potential gives an upward deflection, and the other pole is connected to a Wilson central terminal, and the corresponding records are obtained. Goldberger disconnects from the common terminal the limb that is being explored and does not employ the usual resistances, thus simplifying the technique without altering the results. If Wilson's method is used, the leads are called VR, VL, and VF for the right arm, left arm, and left leg respectively. If Goldberger's technique is used, the letter a (meaning augmented, because the resistances have been removed from the common terminal) precedes the foregoing nomenclature, *i.e.*, aVR, aVL, aVF.

Intracardiac leads.[1] Exploration of the cavities of the heart by the introduction of a catheter through a vein or an artery has often been performed in man. Sometimes it is complemented by recording the intracardiac electrogram.

The catheter in the auricle or the ventricle is connected with the exploratory electrode, and the circuit is completed by means of a Wilson central terminal.

Einthoven's law. Einthoven deduced from a mathematical analysis of his triangle that the height of R in lead II should be equivalent to the algebraic summation of the heights of R in leads I and III. Usually the ECG is obtained by successive, not simultaneous, recording in the three leads; for this reason the experimental results are in only approximate, but nevertheless fairly satisfactory, agreement with the theoretical predictions.

Interpretation of records obtained with precordial leads. According to Wilson and his associates[1] precordial leads serve much the same purpose in the clinical exploration of the heart as the direct unipolar leads introduced by Lewis and Rothschild[2] in the experimental study of the spread of excitation in the dog's heart. The process of excitation by means of these leads can be examined at the point at which it arises, and as it spreads through the heart until it is completed. The method is especially valuable for the exact diagnosis of ventricular hypertrophy, bundle-branch block, and coronary occlusion. Records taken from different points must be compared in order to obtain useful information; the record given by a single precordial lead has little or no significance. The number of precordial leads used should be such as to give adequate data about the electrical changes taking place in both ventricles. All the six leads mentioned should be used, and in certain cases others should be added.

Records obtained with precordial leads can be interpreted by comparing them with those obtained by unipolar exploration of the surface of the heart in experimental animals. The spike of the main upward deflection of the rapid ventricular complex (R), according to Wilson and his associates, marks the beginning of the intrinsic electrical potential, *i.e.*, that occurring in the spot under the electrode; therefore it is a sign of excitation of the cardiac fibers in this place. If this occurs early in the cycle the R wave is usually small and is followed by a deep S. R becomes larger and S smaller as excitation takes place later, and sometimes a Q wave precedes R. The aspect of the QRS complex is, therefore, determined by the way in which the fibers under the electrode are excited, in relation to the spread of excitation throughout the whole myocardium.

Precordial lead records in normal subjects. Records obtained with electrodes placed on the right side of the precordial area show a small R wave, which soon reaches its peak, followed by a deep S (Fig. 65, CV_1). According to Wilson this type of record is due to the fact that the excitatory state, spreading outward, reaches the surface of the right ventricle before it does that

of the left ventricle because of the greater thickness of the wall of the latter. Leads taken from the left side show a large R, with a late peak, frequently preceded by a small Q, and followed by a small S (Fig. 65, CV_6). The Q wave (when it exists) is apparently due to registration of the potential in the cavity of the ventricle (which remains negative throughout the QRS complex) at a moment in which the fibers between the cavity and the electrode have not yet entered into activity. Ventricular complexes of records taken with the electrode placed in the center of the precordial area are intermediate between the two former types (Fig. 65, CV_3). The situation and dimensions of this intermediate area vary in different subjects; its center is usually under lead C_3. The causes determining these variations are still unknown.

FIG. 65. Electrocardiograms obtained from a normal subject with the usual (upper three records) and precordial leads. Wilson's terminal was used. Note how R increases and S diminishes as the exploring electrode is displaced from right to left (CV_1 to CV_6) on the precordial area. (*Courtesy of Dr. J. L. Gilbert.*)

The T wave in the precordial leads of normal adults may be inverted in C_1, but not in records with the other leads.

The duration of the QRS complex is always less than 0.1 sec. in normal subjects. The peak of R in records of leads on the right usually precedes the peak of R in left-side leads by 0.02 sec.

Precordial lead records in abnormal conditions. In certain pathologic conditions records taken with precordial leads show variations with respect to those of normal subjects.

Hypertrophy of the left ventricle causes the following changes to appear:

1. The maximum voltage of the largest QRS deflection is, on an average, greater than in normal subjects.
2. QRS lasts 0.10 to 0.11 sec.
3. Leads from the right side of the precordial area give a small R wave, which may even be absent.
4. The intermediate area is shifted to the left.
5. Leads from the left side give a large R, with late peak, and the T wave is usually inverted.

Hypertrophy of the right ventricle causes changes in the opposite direction of those just mentioned. Right-side leads give a very large R wave, some-

times preceded by a Q wave; S is small or absent, and T is usually inverted. Records from the left side are similar to those given by leads placed on the right side in normal subjects, *i.e.*, R is small or absent, S is large, Q is missing, and T is an upward deflection.

Intraventricular block gives records similar to those of ventricular hypertrophy, but in bundle-branch block the QRS complex always lasts more than 0.11 sec. and the main wave (R or S) has a wide base and is split or splintered.

In cases of *left bundle-branch block*, right precordial leads show a large descending wave, frequently splintered, sometimes preceded by a small R with an early peak. The small R and large S are apparently due to early stimulation of the right ventricle, and the long duration of the QRS complex is due to the delay in stimulation of the left ventricle. Left-side lead records (CV_5 and CV_6) show a single split or splintered R wave with a wide base. The intermediate area is shifted to the left. The T wave is usually deflected in the opposite direction from that of the main wave of the QRS complex, *i.e.*, upward (positive) in right-side leads and downward (negative) in left-side leads.

In cases of *right bundle-branch block*, right-side leads show an R wave varying in height (the descending limb of which may not reach the base line), followed by a second wave, known as R′. The aspect is that of an M with the second peak higher than the first. As the electrode is displaced toward the left, the height of the first wave increases and R′ becomes smaller. Left-side leads show a single high and narrow R wave followed by a deep S, and sometimes preceded by a Q wave. According to Wilson, the R wave in right-side leads is caused by excitation of the ventricular septum, and R′ to delayed excitation of the right ventricular wall under the electrode at a moment when electric forces of opposite sign are not arising in other parts of the myocardium.

Coronary occlusion does not always produce changes in the ECG taken with the usual leads even when it causes an infarct in the myocardium; therefore precordial leads are particularly useful in the diagnosis of this condition. Typical changes are

1. Shifting of the ST segment above or below the isoelectric base line.
2. Negative T wave.
3. Deep Q waves with a wide base (0.04 sec. or more).

The precordial ECG varies in the course of the disease in the same way as the usual ECG. Deviation of the ST segment occurs immediately, and disappears after a few days or weeks; changes in the T wave may persist for months.

Table 17. Electrocardiographic Position of the Heart

Position	*QRS in*	*Shape of QRS*

	VF	Similar to those in CV_5 and CV_6
Intermediate.....	VL and VF	Similar to those in CV_5 and CV_6
Semihorizontal...	VL	Similar to those in CV_5 and CV_6
	VF	Small
Horizontal.......	VL	Similar to those in CV_5 and CV_6
	VF	Similar to those in CV_1 and CV_2

According to Wilson and associates.

Interpretation of records obtained with unipolar limb leads. *Electrocardiographic position of the heart.* The increasingly frequent use of monopolar leads has given rise to the idea that deflections registered by leading off cardiac potentials from a point on the surface of the body are similar to those which would be obtained if the electrode were placed directly on the surface of the heart at the spot nearest the exploring electrode. This idea and the possibility of using an indifferent electrode such as Wilson's common terminal have led to the belief that records of potentials in each one of the limbs (right arm, left arm, left leg) during the cardiac cycle might give important data on the orientation of the heart.

In the normal position, potentials arising in the ventricular cavities, which are negative, are regularly transmitted to the right arm, and deflections arising in the right and left ventricular surface are transmitted in varying degrees to

the left leg and left arm. The shape of the potentials registered in the left arm and leg ultimately will depend on the position of the heart with respect to its own longitudinal axis. As the heart becomes more horizontal, transmission of potentials from the surface of the right ventricle to the leg increases. According to Wilson and his associates, monopolar leads from the limbs give records which define five electrocardiographic positions of the heart (Table 17).

Unipolar limb leads and standard limb leads. The three standard leads I, II, and III are closely related to the three monopolar leads from the limbs. If the values of any two are known, the values of the other four can be calculated.

The sum of the potentials from the three limbs, represented by the angles of Einthoven's triangle, equals zero at any moment of the cardiac cycle, *i.e.*, VR + VL + VF = 0. Therefore, taking into account the conventional polarity used in obtaining the records,

$$L_{I} = VL - VR$$
$$L_{II} = VF - VR$$
$$L_{III} = VF - VL$$

Other applications of monopolar limb leads. Monopolar limb leads can give valuable information for the diagnosis and localization of myocardial infarcts. In some cases the characteristic changes appear in only one of these monopolar limb leads.

PRACTICAL SIGNIFICANCE OF THE ELECTROCARDIOGRAM

A careful study of the electrocardiogram gives information on the spread of excitation to the different chambers of the heart. It tells where the impulse originated and whether it spread along normal or abnormal paths, at normal or abnormal speed. It gives no information whatsoever on the mechanical vigor of the heartbeat. The electrocardiogram is of real value in the establishment of a correct diagnosis in cases of abnormal cardiac rhythm and in cases of myocardial damage resulting from impaired blood supply or from toxic or infectious conditions.

CHAPTER 16

The Excitation of the Heart

RHYTHMICITY IS ONE of the fundamental and more remarkable properties of the heart. It is characterized by the capacity of the heart to generate within itself periodic impulses that will determine its activity.

Rhythmicity is inherent in the cardiac muscular fiber, but it is not equally developed either in all fibers or in the different parts of the heart. If we consider this organ as a whole, it is obvious that the portion with more developed rhythmicity—the one, therefore, that will be able to generate more impulses in unit time—will impose its own rhythm on the entire organ. This is what actually happens.

NORMAL EXCITATION OF THE HEART

The sinoauricular (S-A) node. The normal pacemaker. In mammals, under normal conditions, the impulses that determine the heartbeat are originated in the sinoauricular (S-A) node, a vestigial remnant of the sinus venosus of fishes and amphibians. It is formed by a relatively small mass of cardiac muscle showing a peculiar histologic aspect and with certain chemical characteristics. This structure is called the "normal pacemaker" of the heart because of its particular significance in cardiac activity; it is located in the sulcus terminalis, formed by the superior vena cava and the posterior wall of the right auricle. It is also known as "Keith and Flack's node," after its discoverers.[1]

The fibers of the S-A node are less differentiated than the ordinary fibers of the myocardium, the striation is less marked, and the glycogen content is lower. They are surrounded by dense connective tissue.

It is relatively easy to demonstrate that the S-A node is the normal pacemaker of the heart. This can be done in several ways, all equally convincing.

Changes in temperature localized on the S-A node modify the heart rate; they do not produce this effect when they occur in any other part of the heart. Thus if a test tube filled with warm or cold water is placed on different parts of the heart, there is no change in heart rate except when the tube is placed on the sulcus terminalis, *i.e.*, near the S-A node. In this case, if the tube contains warm water, the heart rate will increase, and it will diminish if the water is cold.

Exploration of the heart with adequate electrodes shows that the first place in which potential differences occur is the region of the S-A node.

If the S-A node is extirpated, the cardiac rhythm changes; the heart rate diminishes, and auricles and ventricles seem to beat simultaneously. Electrocardiograms recorded under the new circumstances will also show that the heart is beating with an abnormal rhythm. This experiment proves, furthermore, that the S-A node is not the only center of cardiac rhythmicity.

The S-A node is therefore the part of the heart which, under normal conditions, because of its peculiar metabolism, originates the greatest number of impulses in unit time, thereby imposing its own rhythm on the rest of the heart. The normal heart rhythm is known as the sinus rhythm, because of its origin. Its basal frequency of discharge is 75 to 80 impulses per minute.

Auricular excitation. The impulse originated

[1] KEITH, A., and M. FLACK, *J. Anat. & Physiol.*, **41**, 172, 1907.

in the S-A node spreads to the auricle and is propagated in all directions, so that all the fibers are excited. Special paths for the conduction of the impulse have not been anatomically differentiated. Nevertheless, electrical exploration has shown that the impulse travels more rapidly
Fig. 66. Diagram of the excitation and conduction system of the heart. 1, sinoauricular node; 2, auriculoventricular node; 3, bundle of His; 4, right branch of the bundle of His; 5, left branch of the bundle of His; 6, Purkinje's system. The arrows indicate the direction in which excitation spreads through the auricular and ventricular muscle.

toward the left auricular appendage and toward the A-V node than to other parts of the auricle. In the dog, Lewis observed velocities of 0.5 to 1.2 m. per sec. in the different directions. In man direct exploration of the heart, using Lewis's method, has shown that excitation spreads at 1.8 to 2.7 m./sec., *i.e.*, twice the speed found in dogs.[1]

The auriculoventricular (A-V) node. In the posteroinferior part of the interauricular septum, near the opening of the coronary sinus, there is a muscular formation known as the auriculoventricular node or the Aschoff-Tawara node.[2] It is an important center of rhythmicity

[1] Kossman, C. E., J. Brumlik, and S. Briller, *J. Clin. Investigation*, **26**, 1186, 1947.

[2] Tawara, S., "Das Reizleitungssystem des Saugetierherzens," Jena, 1908.

and the origin of the bundle of His.[1] This muscular bundle forms a connecting bridge between the auricles and the ventricles and is therefore of special physiologic importance.

The A-V node is made up of two parts, anatomically separated and embryologically different. The upper, auricular, or coronary part develops from the primitive sinus tissue, and its fibers, like those of the S-A node which also have the same origin, have a low glycogen content. The lower, or ventricular part of the node evolves from the auricular canal; its fibers are larger and richer in glycogen than those of the upper part. The bundle of His emerges without any transition from the ventricular portion of the A-V node.

In normal conditions the A-V node acts as a relay station for the impulses originated in the S-A node. On reaching the A-V node the impulses are delayed as if they had to overcome an obstacle. The speed of the impulse in this region has been calculated to be 0.2 m. per sec. (in the dog). This delay permits auricular contraction to end before excitation of the ventricles begins.

In abnormal conditions, when the normal pacemaker is not functioning, or when the rhythmicity of the A-V node is increased to a level above that of the S-A node, the A-V node takes over the functions of pacemaker. The prevailing rhythm is then called an A-V nodal rhythm. When it is established because the S-A is not functioning, the heart rate is about 50 beats per minute, and auricles and ventricles beat almost simultaneously. The nodal rhythm will be considered in greater detail further on.

Ventricular excitation. From the A-V node the impulse spreads rapidly through a specialized connecting system made up of functionally differentiated myocardial fibers, thus reaching all the muscle fibers of the ventricles. The conducting system is formed by the bundle of His, its branches, and the Purkinje network.

The bundle of His is continuous with the ventricular portion of the A-V node. It passes through the A-V septum and goes forward and downward to the membranous portion of the interventricular septum. It soon divides into two branches, right and left, one for each ventricle. These branches subdivide many times and thus make multiple connections with a subendocardiac network formed by special fibers,

[1] His, W., *Arb. a. d. med. Klinik*, **14**, Leipzig, 1893.

histologically and chemically similar to those constituting the bundle of His. They are called Purkinje fibers. Offshoots from this network penetrate between the ordinary muscle fibers of the ventricular walls. Figure 66 is a diagrammatic representation of the conducting system in the heart of mammals. The A-V node and the bundle of His and its branches have been demonstrated by dissection in the human heart.[1]

The impulse spreads through the bundle of His, its branches, and the Purkinje network at a speed of 5 m. per sec. (in the dog). This great speed results in a very rapid entrance into activity of all the ventricular muscle fibers. The whole process takes about 0.07 sec. in the dog (Lewis). The speed of conduction in the contractile myocardium is around 0.5 m. per sec., *i.e.*, ten times less.

The duality of the myocardium. In the heart there is therefore a complete system made up of nodes and special pathways, which originates and transmits the impulse successively and in an orderly way to the different parts of the organ. The fibers of this system, as already stated, have peculiar histologic and chemical features. There are therefore two types of myocardium: one constituting the excitation and conduction system, with the properties of rhythmicity and conductivity especially developed in its fibers, and another (the common myocardium) making up most of the muscular walls of the heart, with contractility as its most prominent property (contractile myocardium).

Varieties of sinoauricular rhythm. In man, under normal conditions, the S-A pacemaker originates and sends out 75 to 80 impulses per minute at remarkably constant intervals, thus determining the normal heart rate. This can be modified by the isolated or joint action of several factors, such as nerve impulses, hormones, drugs, temperature changes, etc. The number of impulses originated in unit time can either increase, in which case there will be a sinus tachycardia, or decrease, in which case there will be a sinus bradycardia.

The impulses are not always sent out from the S-A node with perfect regularity. During inspiration very often the heart rate is greater than during expiration. This sinus arrhythmia, or respiratory arrhythmia, is not abnormal; it is due to nervous influences carried to the heart by its extrinsic nerves, whose nuclei of origin are subject to the variable activity of the respiratory center. This type of arrhythmia is frequent in children and young people, and a marked sinus arrhythmia is almost constantly observed in the dog.

[1] WIDRAN J., and M. LEV, *Circulation*, **4**, 863, 1951.

In all cases of sinus arrhythmia, the heartbeat is normal in so far as the order in which excitation spreads to the different parts of the heart is concerned; neither is the nature of the contraction altered, only the duration of the cycle—specifically, ventricular diastole.

The electrocardiogram always shows a complete set of normal deflections (P, Q, R, S, and T) at each cycle, without any change in shape, in sequence, or in the intervals between them. The only changes consist in a greater frequency in tachycardia, or a lesser one in bradycardia, and the irregularity of the intervals between the complexes, should a sinus (respiratory) arrhythmia be present.

The changes in the sinus rhythm are not necessarily abnormalities. Changes in heart rate are usually physiologic mechanisms of adaptation to the conditions in which the heart is working (exercise) or the result of emotional states.

ABNORMAL EXCITATION OF THE HEART

The normal excitation of the heart is due to impulses originated in the S-A node and transmitted by the pathways that have just been described. This is also the mechanism that assures the greatest efficiency of the heartbeat. There are, however, many causes that frequently disturb the process of excitation in different ways, thus determining more or less important alterations in cardiac and circulatory dynamics. The fundamental aspects of abnormal rhythms will be considered here, because of the great contributions experimental physiology has made in throwing light upon their mechanism, and also because the normal functions of the heart will be more clearly understood through the analysis of the many resources and mechanisms available within itself to assure its efficiency, even when the normal processes have been greatly disturbed.

Abnormal Heart Rhythms

The sinus rhythm is sometimes called the normotopic rhythm. Rhythms originated in

other parts of the heart are called ectopic rhythms. If the abnormal rhythm is originated in some part of the excitation-conduction system it is called homotopic, and heterotopic when it originates outside this system (Hering). Ectopic rhythms develop when the excitability of the normal pacemaker is either depressed or abolished, or when excitability is abnormally increased at some lower focus. Pathological studies suggest, as an important cause of these disturbances, nutritional alterations due to vascular lesions affecting the involved region.
FIG. 67. Upper nodal rhythm (records of a human case). Phlebogram, phonocardiogram, electrocardiogram, and time in 0.2 sec. Note the brief duration of the PR interval in the ECG, the closeness of *a* to *c* in the venous pulse, and the reinforcement of the initial vibrations of the first heart sound. The auricular sound and the normal third heart sound are also registered. In the two last beats the second sound is reduplicated (split).

A-V nodal rhythm. If the S-A node is depressed or has lost its activity, the A-V node takes over the command of cardiac activity and an A-V nodal rhythm is established. The A-V node being a complex one, several types of A-V nodal rhythm may develop.

A nodal rhythm may develop in the upper, middle, or lower part of the A-V node. Such rhythms are called upper, middle, or lower nodal rhythms respectively. They are easily recognized in the ECG (Figs. 67, 68, 69). In cases of upper nodal rhythm the P wave (sometimes inverted) immediately after its commencement is hidden by the QRST ventricular complex. The interval between the beginning of P and the beginning of the ventricular complex (PR interval) is reduced, varying from 0.02 to 0.04 sec. (Fig. 67). In cases of lower nodal rhythm P (usually inverted) appears between the initial ventricular complex (QRS) and the final wave T, the P wave being nearer to the initial complex than to the final one. Finally in cases of middle nodal rhythm P is marked at the same time as QRS and is therefore "absorbed" and concealed by the initial ventricular complex; there is no P wave in the electrocardiogram (Figs. 68 and 69). Nodal rhythms are usually very regular.

If the A-V nodal rhythm results from the absence or functional depression of the S-A pacemaker, the heart rate is low, around 40 to 50 beats per minute. If, on the contrary, it is due to an increased rhythmicity of the A-V node, the frequency of discharge of the latter is greatly enhanced and an A-V nodal tachycardia is the result.

The A-V node can send out occasional impulses when the preponderant rhythm is of S-A origin. A-V nodal premature contractions (extrasystoles) are thus brought about; they have all the mechanical and electrocardiographical features of the A-V nodal beats. These extrasystoles can be originated in the upper, lower, or middle portions of the A-V node.

Idioventricular rhythms. When the normal S-A impulses, or any other stimulus of supraventricular origin, cannot spread to the ventricle because of a functional disturbance or on account of anatomical discontinuity of the His bundle, the ventricles do not stop beating. A center of rhythmicity may arise in any part of the ventricular myocardium (most frequently in the His bundle below the site of interruption) and become the pacemaker for the ventricles. The rhythm thus established is called an idioventricular rhythm. When beating with this type of rhythm the heart rate is always slow, around 30 beats per minute. Idioventricular rhythms will be considered in greater detail when dealing with heart block, a condition with which they are always associated.

Disturbances in Impulse Conduction

When the capacity to conduct impulses is diminished or suppressed in any part of the conducting system, it is said to be blocked. The degree and localization of block varies and can cause a greater or lesser disturbance in the activation of the heart. The principal types of

block are the following: (*a*) sinoauricular (S-A) block; (*b*) auriculoventricular (A-V) block; (*c*) bundle-branch block; (*d*) arborization (intraventricular) block.

Sinoauricular block. The impulse is originated in the S-A node but does not spread outside the node; therefore the auricular muscle is not stimulated. In the simplest form one or more auricular or ventricular contractions occasionally do not occur; there are "dropped beats." If the block is permanent, an A-V nodal rhythm is established. In the first type the diagnosis can be made by examining the electrocardiogram. The record shows a normal S-A rhythm with an occasional abnormally long diastole, which added to the preceding systole lasts as long as two complete cycles.

If there is complete S-A block, the ECG shows an A-V nodal rhythm, without any signs of S-A activity. The diagnosis of sinoauricular block is difficult to establish, because the A-V nodal rhythm might have been originated in some other way.

FIG. 68. Experimental middle nodal rhythm. ECG (lead II) of a dog in which the S-A node has been destroyed. Direct inspection of the heart showed the auricles and ventricles beating at the same time. There is no P wave; it has been "covered" by the ventricular complex. The arrow points to "splintering" of R. Time in 0.04 sec.

FIG. 69. Record of a human case of middle nodal rhythm. The heart contracts regularly at a rate of 50 beats per minute. There are no P waves; the ventricular complexes are normal.

Auriculoventricular block. This type of block is due to functional depression or anatomical destruction of the bundle of His. Three degrees of block can be produced, experimentally[1] or by disease.

1. *Incomplete A-V block.* The impulses are transmitted with difficulty from the auricle down the bundle of His. There is a prolonged interval between the auricular and ventricular contractions. In the ECG the PR intervals last longer than 0.18 sec. (Fig. 70). In the phlebogram there is an interval of more than 0.2 sec. between waves *a* and *c*.
2. *Partial A-V block.* Some but not all the impulses pass down the bundle of His and stimulate the ventricles. In the ECG some of the P waves are not followed by a ventricular complex (Figs. 42 and 71). In the phlebogram isolated *a* waves can occasionally be recognized (Fig. 42). The cases of partial A-V block are classified according to the ratio between auricular and ventricular beats: 2 : 1, 3 : 1, etc. In some cases there are groups of beats in which the obstacle to the passage of the impulse increases at each successive beat. Thus the PR interval of the first beat is normal (0.18 sec.), that of the second beat is more prolonged, and still more that of the following; finally the fourth P

[1] ERLANGER, J., and A. D. HIRSCHFELDER, *Am. J. Physiol.*, **15**, 153, 1906; **16**, 160, 1906.

wave is not followed by a ventricular complex. The series commences again at the next beat, and so on. These groups (described by the Italian physiologist Luciani) can be made up of a greater or lesser number of beats. The long pause between two series of beats gives time for the complete recovery of excitability, and the following impulse is transmitted at normal speed. This long pause is sometimes called a Wenkebach period.

3. *Complete A-V block.* In this type no impulses are transmitted from the auricles to the ventricles. The auricles beat with one rhythm and the ventricles with another. If the auricles are stimulated by normal S-A impulses, the basal frequency will be 75 to 80 beats per minute, while the ventricles beat with a slower rhythm (idioventricular rhythm) of about 30 beats per minute. In the ECG the P waves are more numerous than the QRST complexes, and there is no definite relation of one to the other, as each has a completely independent origin (Fig. 72). The interpretation of the phlebogram (Fig. 72) presents considerable difficulty in some of these cases.
FIG. 70. Incomplete experimental A-V block. Stimulation of the left vagus nerve (beginning at the arrow) prolongs the P-R interval.
FIG. 71. Partial experimental A-V block. Stimulation of the left vagus nerve with a stronger current than the one used in the experiment recorded in Fig. 70 provokes partial A-V block. Some of the P waves are not followed by ventricular complexes. Every second auricular beat is followed by a ventricular complex. With even stronger stimulation of the vagus it is possible to provoke a complete A-V block.

Bundle-branch block. In this case the obstacle to the spread of the impulse is located in one of the branches of the bundle of His. Excitation of the corresponding ventricle is therefore delayed with respect to that of the ventricle with a normal conduction system. This condition has been produced experimentally[1] and asynchronic contraction of the ventricles has been demonstrated in the intraventricular pressure curves recorded with optical manometers. A

[1] BRAUN MENÉNDEZ, E., and L. A. SOLARI, *Rev. Soc. Argent. de biol.*, **12**, 331, 1936; **13**, 33, 1937.

delay of 0.04 to 0.06 sec. has been observed in the contraction of the ventricle with a severed branch with respect to the contraction of the other ventricle.

The ECG allows the recognition of a bundle-branch block. The rapid part of the ventricular complex is widened and notched. It lasts more than 0.10 sec. and is followed by a large and wide T, usually in the opposite direction to the initial part of the complex. The precordial ECG shows typical changes which permit the diagnosis of the bundle branch which is blocked (see Chap. 15).

Arborization block. There are cases in which the electrocardiogram shows ventricular complexes of little amplitude in all the leads. The initial and final deflections are poorly marked; they are of a vibratory nature, and the initial one lasts more than 0.10 sec. The T wave is usually in the same direction as the initial complex. These cases are interpreted as due to diffuse and extended lesions affecting the Purkinje network.

FIG. 72. Complete A-V block. Phlebogram, phonocardiogram, and ECG in a patient with complete heart block. Time in 0.2 sec. The phonocardiogram shows auricular sounds (*A*) coinciding with *a* waves in the venous pulse and P waves in the ECG. The auricular sound is produced even when the ventricle is in systole and the A-V valves are closed.

PREMATURE CONTRACTIONS AND PAROXYSMAL TACHYCARDIAS

An impulse can be originated in any part of the myocardium where a foreign stimulus acts or where the rhythmicity is enhanced, and thence it can spread over the whole heart. If these abnormal stimuli act occasionally and provoke isolated contractions, the resultant beats are called extrasystoles, or premature contractions, because they anticipate the contraction to be produced by the impulse from the pacemaker that at the time sets the fundamental rhythm of the heart. An extrasystole (or premature contraction) is therefore an anticipated systole provoked by an abnormal impulse. According to the location of their origin they are called "auricular," "A-V nodal" (auriculoventricular), or "ventricular" extrasystoles.

In some cases abnormal stimuli act repeatedly, causing a series of extrasystoles, which may be quite short or may last for some time, producing what is known as paroxysmal tachycardia. The frequency of the heartbeat is considerably above the normal (200, 300, or even more beats per minute). Usually the tachycardia begins and ends suddenly. It can be originated in the auricles, the A-V node, or the ventricles.

The dynamic effects of a premature beat depend on the site of origin of the impulse that originates it and on the path along which it spreads. The later in diastole its occurrence, and the nearer to the normal the path along which

it spreads, the greater will be the dynamic efficiency of a premature beat. An auricular extrasystole which takes place just before the normal systole would have occurred has a dynamic effect not greatly different from a normal systole. On the contrary, an early ventricular extrasystole will have little efficiency; the ventricles will be almost empty and the impulse will be transmitted slowly along abnormal paths.

Auricular extrasystoles. The abnormal impulse may act or can be originated in any part of the auricles. During systole there is complete inexcitability. The nearer to the S-A node and the later in diastole the impulse arises, the more similar will the premature contraction and its consequences be to a normal systole.

As even a normal S-A rhythm may show certain irregularities sometimes, only the ECG will reveal the true nature of the auricular extrasystole. Not only is the beat anticipated; there are also changes in shape, amplitude, duration, and direction of the corresponding P wave. The following ventricular complex usually shows no marked anomaly.

The ventricular diastole following an auricular extrasystole is usually longer than the normal diastole, and it lengthens as the premature contraction occurs later in diastole. Nevertheless the sum of the extrasystolic cycle and the preceding normal cycle is seldom equal to two normal cycles, as is usually the rule in ventricular extrasystoles.

A-V nodal extrasystoles. The abnormal impulses arise in this case in the A-V node. They can be originated in the upper, middle, or lower part of the node. The ECG is that of the corresponding nodal rhythm, previously described.

Ventricular extrasystoles. Ventricular extrasystoles can be produced by external or intrinsic stimuli, acting on any part of the ventricles at any moment of diastole. Except for the rare cases in which the origin is in some part of the bundle of His, the impulse spreads along abnormal pathways. Usually the impulse starts in one of the ventricles; it spreads at low speed, and therefore the ventricles contract asynchronously.

Auricular
Ventricular

FIG. 73. Compensatory pause. Auricular contractions are diagrammatically represented in the upper tracing and ventricular contractions in the lower. The third ventricular beat is premature. The normal impulse from the auricle arrives at the ventricle when it is in systole, and therefore during the refractory period. The ventricle does not respond to this impulse, and contracts only when the following normal impulse arrives. The two consecutive cardiac cycles, which include the premature beat, last as long as two consecutive normal cardiac cycles.

The ventricle where the impulse started contracts first. In some cases the impulse may spread antidromically along the His bundle to the auricles and provoke also an auricular systole.

The dynamics of the heartbeat are disturbed in ventricular extrasystoles much more than in any other type of premature contraction. If the contraction takes place very early in diastole, its efficiency is practically nil. If it occurs somewhat later, blood may be ejected into the arteries, but the contraction is always hypodynamic.

The ECG shows typical changes when ventricular extrasystoles occur. An atypical ventricular complex appears after an interval shorter than normal, with no preceding P wave. The initial part of the complex is widened and notched, lasts more than 0.10 sec., and is followed by a prolonged T wave in the opposite direction to the initial deflection.

The diastole following a ventricular extrasystole is visibly prolonged. It is usually called a compensatory pause. The duration of a normal cycle plus that of the extrasystolic cycle usually lasts as long as two normal cycles. This is due to the fact that ventricular extrasystoles in most cases do not disturb the fundamental S-A rhythm (Fig. 73). When the normal impulse from the pacemaker spreads to the ventricles, it finds them in the systolic refractory state caused by the extrasystole, or having not yet completely

recovered their excitability, and therefore unable to respond. Only the following impulse from the S-A pacemaker will provoke a contraction.

Paroxysmal tachycardias. These are due to a succession of extrasystoles; an ectopic focus commences to discharge impulses at a considerably higher frequency than that of the normal pacemaker. The ectopic rhythm can have its origin in the auricles, the A-V node, or the ventricles. Usually the attack begins and ends suddenly, hence the name of paroxysmal tachycardia (Fig. 74).

The ECG allows the recognition of the origin of the extrasystoles causing the tachycardia, but in some cases even with the help of the ECG it is difficult to make an accurate diagnosis.

Auricular flutter. If the frequency of an auricular tachycardia is 300 or more per minute, the auricles beat regularly but the bundle of His cannot conduct at such a high rate; therefore not all the impulses are transmitted to the ventricles, and a 3:1 to 4:1 A-V block is established. The A-V block may be a total one (Fig. 75). The name of flutter is given to this condition because the flapping of the auricular appendages suggests the fluttering of a bird's wings.

Probably in paroxysmal tachycardia— whatever its origin—and in flutter, processes of circular excitation, such as those discussed when the physiologic properties of the myocardium were considered, come into play. Experimental

FIG. 74. Short paroxysmal tachycardia of ventricular origin, occurring spontaneously in a dog. A series of ventricular extrasystoles, in which there is marked lengthening of the QRS complexes, and deep inverted T waves.
FIG. 75. Experimental auricular flutter, complete A-V block, and bundle-branch block. Phlebogram, ECG, and time in 0.2 sec. Rough handling of the auricles caused auricular flutter in a dog in which the bundle of His had been cut. The ECG also shows there is a bundle-branch block. (*Courtesy of Dr. A. Caeiro.*)

damage of the auricular wall in the intervenous area facilitates the development of auricular flutter in the dog; the frequency of auricular beats is directly proportional to the size of the area destroyed.[1]

Incoordinated Excitation. Auricular and Ventricular Fibrillation

In all the cases considered so far, the process of excitation is produced in an orderly way, and a coordinated contraction of the heart muscle results. The excitability of the heart is such that in certain conditions a disorderly process of excitation can be established, characterized by the simultaneous presence of fibers in contraction and in relaxation. There is a complicated and constantly changing network of active fibers interwoven into a no less complicated and changeable network of quiescent fibers. The condition is called fibrillation. When the muscular mass is sufficiently great, fibrillation tends to become permanent. Fibrillation can occur in the auricles, in the ventricles, or in both at the same time.

Auricular fibrillation is compatible with life and even with excellent circulatory dynamics. The auricular muscle does not contract coordinately; a fine, irregular tremor moves all its fibers. The efficiency of this type of activity is nil, and the auricles do not propel the blood forward. The ventricular systole is coordinated, but ventricular beats are separated by extremely irregular intervals. Their vigor is also irregular. No two beats are equally vigorous or equally spaced. There is a complete or permanent arrhythmia (delirium cordis). Nevertheless circulatory conditions may be quite satisfactory.

Auricular fibrillation can be provoked in dogs by stimulating the auricles with a tetanizing current. It is usually of short duration; after a few minutes it is gradually transformed into flutter, and then suddenly the normal S-A rhythm is reestablished. There are no P waves in the ECG when there is auricular fibrillation. The ventricular complexes are normal but they are spaced irregularly (Fig. 87). During diastole an irregular vibration of small amplitude is seen in the record, and occasionally a small wave appears which is not sufficiently large to be identified with a P wave. This persisting electrical activity is due to the activity of the auricular fibers.

[1] Rosenblueth, A., and J. García-Ramos, *Acta cardiol.*, Suppl. 2, 87, 1947.

Ventricular fibrillation is nearly always permanent and a relatively common final event, as far as life is concerned, in large animals and in man. Blood is not ejected from the heart and the arterial blood pressure falls to zero. The ventricles become considerably distended by the blood which continues to return to the heart. The large veins are filled with blood.

Several causes may lead to ventricular fibrillation: electric currents of all types, mechanical stimulation, drugs, etc. A frequent cause of ventricular fibrillation is the occlusion of an important branch of a coronary artery.

Ventricular fibrillation has been the most serious immediate complication in a few cases of intracardiac catheterization and surgical operations on the heart. Most of these patients died. When these procedures are carried out, care should be taken to prevent ventricular fibrillation and to have at hand means of controlling it should it occur. In order to prevent fibrillation the heart should not be handled roughly, scratched, or pinched; the endocardial surface is especially sensitive. Certain drugs have an antifibrillating action, *e.g.*, novocainamide.[1] If fibrillation does occur, it is still possible to reestablish coordinated beats, but unfortunately the procedure to do this is not easy to apply in the conditions in which fibrillation usually occurs. The most efficacious treatment consists in the application of an electric countershock: two relatively large electrodes are placed directly on the surface of the exposed heart and a 60-cycle, 5-amp. current of very short duration is passed.[2] While the apparatus is being prepared a certain degree of blood pressure must be maintained by rhythmic compression of the ventricles (heart massage). Electric countershock has been applied successfully in human cases of ventricular fibrillation.[3]

The ECG in cases of ventricular fibrillation shows only a completely irregular and dis-

orderly series of deflections of unequal size and low voltage.

Ventricular fibrillation consists at first of a fairly vigorous twitching of the myocardiac fibers. Gradually these become weaker, and after 10 to 20 min. their activity is reduced to a few weak waves which slowly travel along the heart muscle. When they finally cease the heart muscle is dead.

CHAPTER 17

The Nervous Control of Cardiac Activity

THE HEART HAS within itself all the factors necessary to originate and maintain its activity provided it is in an adequate medium. Rhythmicity and the other physiologic properties are inherent in the myocardial fiber, independently of the nervous tissue included in the heart. Nevertheless the nervous system plays a part in coordinating and integrating the activity of the heart with the needs of the organism in different physiologic circumstances.

The nervous regulation of the heart is accomplished through the autonomic nervous system (Chap. 84). From a functional point of view three systems may be considered in so far as the nervous regulation of the heart's activity is concerned: (*a*) inhibitory; (*b*) accelerator; (*c*) sensory. The conception of an intracardiac, locally integrated nervous system is no longer tenable. Intracardiac ganglia, at any rate in vertebrates, are only relay stations along the efferent paths.

THE CARDIOINHIBITORY SYSTEM

In 1845 E. H. and E. F. Weber[1] demonstrated that stimulation of the vagus nerve in the frog stops the heart in diastole. Up to that time only motor effects had been observed on peripheral nerve stimulation; for the first time an inhibitory effect was obtained. It is now common knowledge that inhibition, although less conspicuous than excitation, is not less important nor less frequent in the physiology of the nervous system. Soon after this pioneer demonstration, the inhibitory effect of the vagus on the heart was observed in many other animal species and the principle was extended to all the vertebrates.

The vagus nerve is part of the cranial parasympathetic division of the autonomic nervous system. The cellular bodies of its efferent fibers are situated in the medulla, in what is known in mammals as the dorsal nucleus. The greater part of the fibers of the right vagus end in the S-A node, the remainder in the A-V node. The greater part of the fibers of the left vagus end in the A-V node, and only a few in the S-A node. For this reason stimulation of the right vagus has a greater effect on the rhythm of the heart as a whole, whereas stimulation of the left vagus usually produces heart block (Figs. 70 and 71). The fibers of the vagus end on ganglion cells, which send out postganglionic fibers to the auricles and the basal portion of the ventricles.

Analysis of the vagal action on the heart. The effects of stimulation of the vagus in the frog, toad, tortoise, dog, cat, and rabbit (animals most frequently used in laboratory experiments) are essentially the same in all species. The animal is anesthetized, and the cervical part of the vagus is dissected; it is cut so that stimulation will not spread to the nerve centers along the afferent fibers and thus provoke unwanted reflex effects. The peripheral end is stimulated, using bipolar electrodes and a tetanizing current from an induction coil. The effects produced can be observed directly on the exposed heart, or indirectly by recording the variations in blood pressure, arterial pulse, the electrocardiogram, or any other aspect of cardiac activity. There is always a short latent period between the application of the stimulus and its effect.

A stimulus of moderate intensity slows the

[1] WEBER, E. H., *Ann. universali di medicina*, **116**, 225, 1845.

heart rate (bradycardia). A strong stimulus stops the heart completely. If the left vagus is stimulated with moderate intensity, complete or partial A-V block is almost always provoked (Figs. 70 and 71). Strong stimulation of the left vagus also brings the heart to a standstill. The arterial blood pressure falls rapidly and reaches zero if the heart is stopped for a sufficient time (Fig. 76, 1). The arterial pulse vanishes and electrical variations connected with the heart's activity disappear completely. (Usually the stimulating current spreads through the body to the electrodes, and may be recorded by the electrocardiograph.)

As soon as vagal stimulation ceases, the heart renews its activity and usually a period of tachycardia follows. The blood pressure rises rapidly to the initial level and for a short time may surpass it. The arterial pulse and the electrical signs of cardiac activity reappear.

Stimulation of the vagus nerve depresses not only the rhythmicity of the heart but also its conductivity and contractility. On the other hand, excitability is not modified; the threshold remains unaltered during stimulation of the vagus. The refractory period, however, is shortened and the threshold of fibrillation is lowered during the vulnerable period.[1] Stimulation thresholds also remain unaltered while the heart is stopped by the effect of acetylcholine.[1]

Vagal action is exerted on the nodal tissues and on the auricular myocardium. The ventricles cease beating because no impulses reach them. When there is a complete A-V block, vagal stimulation does not have any effect on the idioventricular rhythm.
FIG. 76. Vagal action and vagus "escape." Arterial blood-pressure curves registered by a mercury manometer. 1, stimulation of the peripheral end of the right vagus nerve; the heartbeat stops for a time, but begins again in spite of the continuous stimulation (black line) of the vagus. 2, injection of acetylcholine. When the heart is again beating, at 3, the right vagus is stimulated as in 1; "escape" occurs much sooner. Time in 5 sec. (*Diagram of an experiment by A. S. Segura, Rev. Soc. argent. de biol., vol. 14, p. 497, 1938.*)

Mechanism of vagal action. When a heart is perfused and the vagus stimulated, if the perfusion fluid is used to perfuse another heart, it will produce bradycardia in this second heart or stop it, as if the vagus had been stimulated. This fact was interpreted as proof that stimulation of the vagus sets free a chemical substance which diffuses into the perfusion fluid, where it can be demonstrated by its pharmacological effects.[2] This substance, first called the "vagal substance," is acetylcholine. This is a particular instance of the release by nerve stimulation of a chemical mediator for the transmission of the impulses at the synapse and from nerve fibers to effectors (see Chap. 84). Acetylcholine is the chemical mediator in the parasympathetic division of the autonomic nervous system; both the preganglionic nerve endings in the ganglia

[1] HOFFMAN, B. F., A. A. SIEBENS, and C. McC. BROOKS, *Am. J. Physiol.*, **167**, 796, 1951.

[1] MOISSET DE ESPANÉS, E., *Rev. Soc. argent. de biol.*, **26**, 257, 1951; *Compt. rend. soc. de biol.*, **145**, 452, 1951.

[2] LOEWI, O., *Pflüger's Arch. f. d. ges. Physiol.*, **189**, 239, 1921.

and the postganglionic nerve endings on the effectors liberate acetylcholine. The cardioinhibitory system belongs to the cranial division of the parasympathetic.

Intravenous injection of acetylcholine produces bradycardia or stops the heart, according to the dose given. It has the same effect as stimulation of the vagus (Fig. 76, 2). The auricles of a rabbit which have ceased to beat after 24 to 36 hr. of perfusion with Tyrode's solution will begin to beat again if a small quantity of acetylcholine (1:100,000,000 to 1:400,000,000) is added to the perfusion fluid. When the heart has thus recovered its activity, a larger dose of acetylcholine will again stop it.[1] Atropine, an alkaloid extracted from the plant *Atropa belladonna* (deadly nightshade), suppresses vagal inhibition of the heart and the effects of acetylcholine.

During stimulation of the vagus, potassium is also liberated, and as potassium has a depressor activity on the heart, at one time it was thought to be the substance responsible for the action of the vagus.[2] The effect of potassium is not identical to that of stimulation of the vagus, since it is not suppressed by atropine. Probably there is some connection between the liberation of acetylcholine and that of potassium, but its nature has not yet been established.

Muscarine, pilocarpine, and eserine have an effect similar to that produced by stimulation of the vagus, but none of these substances is as perfectly parasympathicomimetic as acetylcholine.

"Vagus escape." If stimulation of the vagus is continued for some time after the heart has stopped, the heart again begins to beat in spite of the persistent stimulation. The heart "escapes" from the influence of the vagus, hence the name of "vagus escape." There are two possible explanations of this phenomenon: either acetylcholine is exhausted by prolonged stimulation, or the heart becomes refractory to the effect of acetylcholine. It is not yet possible to deny the former explanation, but there is proof that acetylcholine soon loses its inhibitory effect on the heart. A sudden increase in the concentration of acetylcholine will again produce cardiac inhibition, but this will also be of a transitory nature even though the concentration of acetylcholine is maintained constantly at the new high level.[1] Acetylcholine behaves, with respect to its cardioinhibitory activity, as a "potential drug."[2] Moreover, stimulation of the vagus after injection of acetylcholine produces a much less marked effect than vagal stimulation without the previous injection of this drug (Fig. 76). These experiments are arguments in support of the hypothesis that "vagus escape" is due to a kind of tolerance of the myocardiac fiber to acetylcholine.

Reflex Cardiac Inhibition

Direct stimulation of the vagus, such as has been considered so far, seldom occurs outside experimental conditions. In physiologic conditions the cardioinhibitory system is stimulated by reflex mechanisms. Some of these mechanisms are activated accidentally and may produce harmful effects. Others are permanent physiologic processes which take part in the regulation of fundamental equilibriums, such as the arterial blood pressure.

Accidental cardioinhibitory reflexes can be provoked by stimulation of any sensory nerve, but from some particular areas marked vagal effects on the heart can be produced. Thus sudden or gradual abdominal compression provokes bradycardia, or even stops the heart (Goltz's reflex) for a sufficient time to cause fainting and unconsciousness (*e.g.*, a knockout blow on the epigastrium). The nasal mucosa when stimulated by chemical irritants, such as formaldehyde, ammonia, chloroform, etc., initiates cardioinhibitory reflexes that are sometimes the cause of serious accidents in the course of anesthesia. Compression of the eyeballs produces bradycardia in subjects with a well-balanced autonomic nervous system (Aschner-Dagnini phenomenon). In Ortner's phenomenon (forced extension of the neck) and Czermak's phenomenon (compression of the carotid at the level of the thyroid cartilage), bradycardia is produced reflexly by changes in pressure in the carotid sinus and not by direct stimulation of the vagus nerve as formerly believed. A sufficient

[1] Moisset de Espanés, E., and C. Martínez, *Rev. Soc. argent. de biol.*, **14**, 528, 1938.

[2] Drugs with "potential action" are those that produce a visible effect only when there is a sudden increase in their concentration. If the concentration remains constant or increases very gradually, they have no effect.

dose of atropine suppresses all these vagal reflexes.

Pressoreceptor areas in the aorta and carotid sinus. Nerves of de Cyon and Hering. The inner surface of the first part of the aorta and the carotid sinus (a dilatation at the beginning of the internal carotid) are the sites of origin of reflex impulses that exert a permanent influence on the cardioinhibitory system (Figs. 77 and 78). Nerve impulses originated in these areas, in special receptors sensitive to pressure changes, are conveyed to the medulla by the cardioaortic and sinus nerves. The cardioaortic nerves or the nerves of de Cyon are formed by fibers arising mainly in the internal layers of the aorta and also to a lesser extent in the endocardial layers of the left ventricle. The fibers arising in the left ventricle and the root of the aorta form the right cardioaortic nerve; the fibers arising in the aortic arch form the left cardioaortic nerve. In man and in the dog the cardioaortic nerves are incorporated in the vagi; in the rabbit they constitute separate nerves. Stimulation of the peripheral end of the cardioaortic nerves, after having cut them in the neck, produces no effect; stimulation of the proximal end, on the contrary, is followed by bradycardia and a fall in blood pressure. For this reason the aortic nerves were called "inhibitory nerves."[1]

FIG. 77. Innervation of the vasosensory areas. 1, heart; 2, aorta; 3, common carotid artery; 4, carotid sinus; 5, external carotid; 6, internal carotid; 7, carotid body; 8, de Cyon's cardioaortic nerve; 9, vagal ganglion; 10, nerve fibers from the carotid sinus to the glossopharyngeal nerve; 11, nerve fibers from the carotid sinus to the vagus nerve; 12, glossopharyngeal nerve; 13, vagus nerve. (*C. Heymans.*)

The fibers of the sinus nerves, also called "nerves of Hering," one on each side of the body, arise in the internal layers of the walls of the corresponding sinus caroticus and immediately join the glossopharyngeal nerve on the respective side. Anatomically the sinus nerves are inconspicuous, and they were not noticed until Hering (1924) drew attention to their functional significance. Afferent stimulation of these nerves is followed by bradycardia and a fall in arterial blood pressure.

FIG. 78. Position of the carotid sinus region in man

The cardioaortic and sinus nerves are sometimes called "pressoreceptor" or "vasosensory" nerves. By recording the action currents of these nerves it has been possible to demonstrate that

[1] DE CYON, E. and K. LUDWIG, *Ber. Sächs. Ges.*. 18. 307, 1866.

when the blood pressure is normal, impulses of low frequency are discharged along their fibers, especially at each systolic rise of pressure. When the blood pressure rises, the frequency of the impulses increases and even during the diastolic fall in pressure the discharge persists (Fig. 79).
FIG. 79. Action currents of a pressoreceptor. Above: nerve impulses from an isolated receptor in the carotid sinus when the arterial pressure was 55 mm. Hg; each series of impulses was provoked by the rise in pressure at each systole. Below: the arterial pressure was raised to 135 mm. Hg; the frequency of the impulses increased considerably, and the discharges continued during diastole. (*Diagram from an experiment by Bronk and Stella, J. Cell. & Comp. Physiol., vol. 1, p. 113, 1932.*)

On the contrary, when the blood pressure falls, the frequency of the impulses diminishes, and when the pressure is very low the impulses cease completely.

The impulses travel along the depressor nerves to the cardioinhibitory center and, through the vagus, cause a decrease in the frequency of the heartbeat. This reflex controls the blood pressure; an increase in blood pressure diminishes the heart rate, and thus the blood pressure is lowered. The effect of these nerves is not limited to the heart rate; the impulses spread to the vasomotor center, and arterial vasodilatation is provoked, which also lowers the blood pressure.

Marey[1] pointed out many years ago the inverse relation existing between the blood pressure and the heart rate (Marey's law).

Changes in the internal pressure of the arteries are not the only efficient stimulus of the pressoreceptors. Compression with a forceps or the fingers, or elongation of the artery by stretching it, also produces a reflex response.

Section of all the cardioaortic and sinus nerves is followed by tachycardia and hypertension, which is permanent in some animals; in the dog, pulse rate and blood pressure gradually return to normal.

Carotid and aortic bodies.[1] At the bifurcation of the common carotid artery, between the internal and external carotid arteries, there is a small structure known as the carotid body. It is made up mainly of vascular sinusoids, the walls of which are of endothelial nature; special cells and a rich nerve plexus complete the structure of this peculiar little organ. The nerves arising in the carotid bodies (one on each side) are not sensitive to distention, but they are stimulated by changes in the chemical composition of the blood, eliciting cardiovascular and respiratory responses. The carotid bodies can be considered as a complement to the carotid sinus. The aortic body situated near the arch of the aorta is similar in structure and function to the carotid bodies. Stimulation of the carotid and aortic bodies by chemical changes in the blood is not of much importance in the regulation of cardiac activity and blood pressure, but it is of great significance in the regulation of respiration (Chap. 32).

Vagal tone. Normal arterial blood pressure stimulates the vascular pressoreceptors, and the impulses from these receptors are constantly stimulating the cardioinhibitory center, which discharges along the vagi nerves. The heart is thus submitted to a continuous inhibitory influence. If both vagi are cut, or atropine is injected into an animal with normal blood pressure, the heart rate increases immediately. The permanent influence of the vagi on the heart is called vagal tone. A decrease of vagal tone is the first step to cardiac acceleration. Respiratory fluctuations in vagal tone determine periodic changes in the heart rate, which increases during inspiration and decreases during expiration (respiratory sinus arrythmia). Distention of the right auricle by an increased venous return also provokes tachycardia (Bainbridge's reflex).[2]

Cardioinhibitory center. The center for the cardioinhibitory reflexes is situated in the medulla. It is composed of cellular bodies from

[1] MAREY, E. J., "Physiologie médicale de la circulation du sang," Paris, 1863, p. 206.

[1] SCHMIDT, C. F., and J. H. COMROE, *Physiol. Rev.*, 20, 115, 1940.

[2] BAINBRIDGE, F. A., *J. Physiol.*, 50, 65, 1915.

which the efferent fibers of the vagus arise, (dorsal nucleus of the vagus) and also of the portions of gray substance where the afferent fibers of the vagus end. The vasomotor center is very close to the cardioinhibitory center, and both centers may be influenced by the same factors. The cerebral cortex may also send impulses to the cardioinhibitory center and modify its activity, as in changes in heart rate due to emotional states. The destruction of the cardioinhibitory center, or its suppression by drugs, abolishes vagal tone and all the cardioinhibitory reflexes.

Trophic action of the cardioinhibitory system. The vagus has a definite effect on cardiac metabolism, favoring the preservation, and recovery through anabolic restoration, of substances that liberate energy on disintegration. In this respect as well, the vagus is antagonistic to the sympathetic.

THE CARDIOACCELERATOR SYSTEM

E. and M. de Cyon in 1867 gave a conclusive demonstration of the existence of nerves that, when stimulated, produced acceleration of cardiac activity. They pointed out, at the same time, the course followed by the fibers.[1] These nerves belong to the thoracolumbar division of the autonomic nervous system. The path of cardioaccelerator fibers has been determined in man by studying the results of therapeutic cervicothoracic sympathectomy. The following conclusions are now well established:[2] (*a*) few, if any, fibers emerge from the spinal cord in the first thoracic nerve; (*b*) the greater part of the fibers form part of the second thoracic nerve; (*c*) important numbers of fibers emerge with the third, fourth, and fifth thoracic nerves; (*d*) the fifth thoracic nerve seems to be the lowest level at which cardioaccelerator fibers leave the spinal cord; (*e*) more fibers emerge on the right than on the left side. This distribution does not vary significantly from that found in other mammals (Fig. 80). The most important group of accelerator fibers passes through the annulus of Vieussens. At this point some of the fibers are still preganglionic; they end on neurons in the inferior and middle cervical ganglia, but most of them are postganglionic fibers that have their cellular bodies in the thoracic ganglia. From the annulus of Vieussens and from the cervical ganglia, the accelerator fibers proceed in the cardiac nerves and end in the heart. Smaller groups of postganglionic fibers go directly from the upper thoracic ganglia to the heart.

Direct stimulation of the cardioaccelerator nerves. The most favorable place for stimulation of the cardioaccelerators is the stellate ganglion, which can be reached from the upper dorsal region without opening the pleura, or after having opened the thorax in an anesthetized animal kept alive by artificial respiration.

The effect of direct stimulation of the accelerator nerves is not so dramatic as the effect of stimulating the vagi. The latent period is longer (it varies between 10 and 20 sec.) and the heart rate increases gradually. The increase in heart rate is greater when the initial frequency is low than when there is already some degree of tachycardia, and it persists for some time after stimulation has ceased. The operation needed to reach the stellate ganglion causes tachycardia, and for this reason the result of experimental stimulation of the accelerators is also less marked than that of vagal stimulation.

Cardiac acceleration is due principally to shortening of the ventricular diastole, but the ventricular systole is also shortened, as Wiggers has shown. This shortening of the systole is more marked in cardioacceleration caused by stimulation of the sympathetic nerves than in tachycardia due to other causes. There is also considerable shortening of systole in adrenaline tachycardia.

The cardioaccelerator effect of the sympathetic is known as a positive chronotropic effect. The other fundamental properties of the myocardium (excitability, conductivity, and contractility) are also increased by sympathetic stimulation. With respect to excitability, only a presumptive conclusion can be arrived at, because adequate and sufficiently accurate methods have not yet been applied in the study of this problem. Sympathetic stimulation favors fibrillation of the heart.

The blood pressure rises when the accelerators are stimulated. This effect is due to the increase in heart rate. The frequency never increases sufficiently to impair the filling of the heart.

The sympathetic system exerts, to a certain extent, a direct effect on the ventricles. In cases of complete A-V block, stimulation of the

accelerator nerves increases the frequency of both auricular and ventricular contractions, but the rhythm of each chamber remains independent of the other.

other adrenergic sympathetic fibers are stimulated (see Chap. 84). According to von Euler,[1] sympathin is made up of adrenaline and noradrenaline in variable proportions. Sympathin

Efferent innervation of the heart. *VN*, vagus nerve; *SCG*, superior cervical ganglion; *MCG*, middle cervical ganglion; *SG*, stellate ganglion; II to VIII *ThG*, upper thoracic ganglia; *WRC*, white rami communicantes; *SCN*, superior cardiac nerve; *MCN*, middle cardiac nerve; *ICN's*, inferior cardiac nerves; *CP*, cardiac plexus; *SAN*, sino-auricular node; *AVN*, auriculoventricular node.

Mechanism of cardioaccelerator action. A chemical mediator—sympathin[1]—is released at the peripheral endings of the accelerator fibers when they are stimulated, just as when any

[1] CANNON, W. B., *et al., Am. J. Physiol.*, **96**, 392, 1931; **97**, 365, 1931; **99**, 398, 1932.

extracted from human, bovine, and porcine hearts is very similar to noradrenaline.[2] Noradrenaline injected intravenously has similar effects on the

[2] RABB, W., and E. LEPESCHKIN, *Circulation*, **1**, 741, 1950.

heart to those of adrenaline, but they are less marked. In man it provokes a sharp rise in systolic and diastolic blood pressure, which causes reflex bradycardia. Atropine abolishes this bradycardia; a cardioaccelerator effect of noradrenaline can be observed only if atropine has been previously injected.

Other drugs of similar chemical structure to that of adrenaline, such as ephedrine, tyramine, veritol, etc., have an effect very similar to that of adrenaline. Nicotine also increases the heart rate. Ergotamine, an alkaloid extracted from the ergot of rye, suppresses the accelerator effect of both sympathetic stimulation and adrenaline injection.

Cardioaccelerator tone. Bilateral removal of the stellate ganglia causes a permanent decrease in the heart rate. This fact has been interpreted as evidence of a permanent "tonic" action of the cardiac accelerator nerves, which is usually masked by the more powerful vagal tone.

Cardioaccelerator center. From a functional standpoint a cardioaccelerator center may be admitted; it is situated near the cardiodepressor center but is not so clearly differentiated. When the cardioaccelerator center enters into activity it provokes a more marked tachycardia than that caused by mere inhibition of the cardiodepressor center. Agents that at first cause inhibition of the cardiodepressor center stimulate the cardioaccelerator center when the intensity of their action increases. This occurs when there is a marked fall in blood pressure, a great distention of the auricles, an intense emotional state, etc.

Trophic action of the cardiac sympathetic. Stimulation of the cardiac sympathetic activates catabolic processes, increasing the consumption and disintegration of substances that thereupon release energy. Oxygen consumption also increases.

THE SENSORY INNERVATION OF THE HEART

The afferent fibers distributed in different parts of the heart provide this organ with a particular form of sensibility, which enters consciousness only in certain conditions. The normal functioning of the heart remains completely outside the sphere of consciousness. Only when the heartbeat increases in strength and frequency, under the influence of exercise, emotions, or stimulating drugs, is it felt as "palpitations." Premature contractions (extrasystoles), especially those of ventricular origin, are also perceived as a sudden and fleeting sensation of constriction, vaguely localized in the cervical part of the respiratory tract, or in the epigastrium.

The heart has no tactile sensibility, as was demonstrated by Harvey in the historic case of the Earl of Montgomery, who had an exposed heart due to thoracic malformation.

From a medical point of view the most important form of sensibility is that of pain, which appears in cases of myocardiac ischemia due to diffuse or localized disturbances in the coronary circulation. The patient experiences a sensation of suffocating contraction localized deeply but diffusely within the chest. There is also a most intense and acute pain referred to the precordial region and the left side of the chest, irradiated along the left arm down to the hand and the fourth and fifth fingers; an agonizing sensation of imminent death completes the picture. This type of pain is known as anginal pain, or angina pectoris.

The course of the nerve fibers along which the impulses responsible for these painful sensations travel has been carefully investigated, mainly with the object of devising surgical procedures for relieving patients in whom the pain has become intolerable because of its intensity and persistence. The nerve fibers leave the cardiac plexus in the middle and inferior cardiac nerves and go to the middle cervical and stellate ganglia on the left side of the body. They pass through these ganglia and down the left sympathetic chain, which they leave in the rami of the first four or five thoracic nerves, penetrating into the spinal cord by the corresponding dorsal roots. Other fibers go directly from the plexus to the first five or seven thoracic nerves. Finally a few fibers join the vagus nerve (Fig. 81). Surgical procedures for the relief of cardiac pain consist in the extirpation of the stellate ganglion on the left side of the body, which interrupts the principal path, or in cutting or destroying with an injection of alcohol, or anesthetizing, the five upper thoracic rami or the dorsal roots of the corresponding thoracic nerves.

Precordial pain and its irradiation along the left arm belong to the type known as referred pain. This type of pain is felt in the somatic structures innervated by the same segment as

the viscera in which the pain has its origin (see Chap. 73).

Inflammation of the pericardium and pericardial effusion also provoke precordial pain irradiated to the neck or the epigastrium.

myocardial fibers. The following are some of the most conclusive demonstrations:

1. When the intracardiac ganglia of the frog's or turtle's heart are extirpated, the organ not only does not stop, but no fundamental change is observed in the sequence of the heartbeats under the new circumstances.
2. Suppression of the activity of the intracardiac ganglia by treating them with nicotine has no disturbing effect on the heartbeat.
3. Small fragments of heart muscle, completely free from nerve cells, contract rhythmically.

THE MYOGENIC OR NEUROGENIC ORIGIN OF CARDIAC ACTIVITY

At one time the nervous or muscular origin of the impulse that causes the heartbeat was the object of considerable debate. The matter seems now to have been settled. In vertebrates there is definite proof that the impulse starts within the

4. In the chick embryo the heart begins to beat before any nervous structure is present.
5. Tissue cultures of myocardium, in which only cardiac muscle fibers are growing, contract rhythmically.

The capacity to conduct impulses is also a property of the myocardial fibers.

The structure and the properties of the heart in the invertebrates vary considerably from one species to another, so it is difficult to arrive at general conclusions valid for all. Thus the heart of snails of the genus *Helix* is made up of plain muscle, while that of the crustacean *Limulus polyphemus* (the horseshoe crab) is constituted of ordinary striated-muscle fibers. Carlson's experiments[1] have shown that in *Limulus* cardiac activity has a nervous origin.

Stannius' ligatures.[2] In the amphibian heart the sinus, auricles, and ventricle beat successively one after the other. If a tight ligature is placed between the sinus and the auricles (Stannius' first ligature), the sinus continues to beat with its normal rhythm but the auricles and ventricle are stopped in diastolic relaxation. If a second ligature is placed between the auricles and the ventricle, rhythmic ventricular contractions reappear. Complete sections produce the same effects as the ligatures. The first explanation given to account for these facts was that Remak's ganglion, situated in the sinus, sends out rhythmic motor impulses that cause the whole heart to beat. A second nervous structure found in the auricle (Ludwig's ganglion) would emit inhibitory impulses, normally overcome by those of Remak's ganglion. Stannius' first ligature would release Ludwig's ganglion from the control of the sinus ganglion, and would therefore inhibit a third ganglion (Bidder's) situated in the ventricle. The latter would be released by Stannius' second ligature from the inhibitory impulses of Ludwig's ganglion and thus could start rhythmical ventricular contractions.

[2] STANNIUS, H. F., *Arch. f. Anat. u. Physiol.*, p. 85, 1852.

The results are not always as typical as currently described in textbooks, and their explanation on the basis of the local ganglionic activity is no longer tenable. The results observed can be more satisfactorily explained by differences in automatism of the myocardium in different parts of the heart. Changes in the tension of the cardiac walls caused by the ligatures also influence the results.[1]

CHAPTER 18

The Nutrition and Work of the Heart

THE FUNCTIONAL INTEGRITY of the heart depends in the first place on the nutrition of its fibers, which in mammals is assured by the blood flowing through the coronary arteries. The coronary circulation has certain peculiarities, and its disturbances may have fatal consequences. For this reason a thorough knowledge of its physiology is of great importance to the physician.

CORONARY CIRCULATION

Anastomoses[1] between the different branches of each coronary artery and also between the territories of the right and left coronary arteries may be easily demonstrated by a variety of anatomical procedures. From a functional point of view, however, the coronary arteries must be considered as terminal vessels. The anastomotic channels cannot compensate adequately for the sudden occlusion of a branch of a certain importance. Sudden occlusion of a coronary artery or of one of its branches causes death of the tissues it nourished, and an infarct is formed. If the subject does not die, scar tissue replaces the dead fibers in the area of necrosis. If occlusion occurs gradually, the anastomoses develop considerably and no infarction occurs when eventually the artery is completely occluded.

The *veins of the heart* run beside the arteries. The majority of the veins run toward, and end in, the coronary sinus, which opens into the lower part of the posterior wall of the right auricle. At this opening Thebesius' valve is found.

[1] PRINZMETAL, M., B. SIMKIN, H. C. BERGMAN, and H. C. KRUGER, *Am. Heart J.*, **33**, 420, 1947. ZOLL, P. M., S. WESSLER, and M. J. SCHLESINGER, *Circulation*, **4**, 797, 1951.

Embedded in the myocardium there are also small short vessels lined by endothelium, which open directly into the cavities of the heart. They are called veins of Thebesius. According to some investigators they communicate with the capillaries of the heart. They are of no value as an auxiliary circulatory system in cases of sudden coronary occlusion, a fact that has been shown by experiments on dogs and in cases of coronary occlusion in man.

Dynamics of the coronary circulation. The circulation in the coronary arteries has certain peculiar features owing to the origin of the arteries in the root of the aorta and their distribution in the walls of the heart, where they are subject to rhythmic compression and decompression at each systole and diastole. It seems definitely established that the velocity of flow decreases progressively, until it almost ceases during systole, and then rapidly increases from the beginning of diastole, to reach its peak in mid-diastole. The myocardium receives during systole approximately three-quarters of the volume of blood it receives during an equivalent period of the diastole, but as the diastole lasts longer than the systole, the proportion of blood that the myocardium receives during diastole is considerably greater (Wiggers).

The pressure in the main branches of the coronary arteries closely follows the changes in the aorta.[1] Figure 82 shows the pressure in the aorta and the arterial pulse in the ramus descendens anterior, simultaneously recorded in

[1] WIGGERS, C. J., and F. S. COTTON, *Am. J. Physiol.*, **106**, 9 and 597, 1939.

a dog. There is perfect coincidence between the curves.

The coronary circulation depends essentially on the difference in pressure between the aorta and the right auricle. It is influenced by the contraction and relaxation of the myocardium and is under the control of the autonomic nervous system, which governs the caliber of the vessels. The innervation of the coronary arteries is also peculiar inasmuch as sympathetic impulses produce dilatation in them, whereas in most other territories they produce vasoconstriction. Constriction of the coronary vessels is provoked by parasympathetic impulses, which travel along the fibers of the vagi nerves. Drugs produce effects according to their sympathicomimetic or parasympathicomimetic activity. For instance, acetylcholine (a parasympathicomimetic drug) produces constriction of the coronary arteries, and adrenaline (a sympathicomimetic drug), dilatation. Muscarine and pilocarpine have the same effect as acetylcholine; atropine, nitrites, and digitalis dilate the coronary vessels.

Coronary blood flow. The coronary blood flow can be measured experimentally by introducing a cannula directly into the coronary sinus and collecting the blood which flows out. This procedure has been used as a standard for calibrating and testing the accuracy of indirect methods that can be applied in man. For example, in the nitrous oxide method the subject breathes a certain amount of nitrous oxide which passes through the lungs into the arterial blood; an intracardiac catheter is introduced through a vein and then through the right auricle into the coronary sinus, and the concentration of nitrous oxide in arterial and in coronary venous blood is determined. The partition coefficient of nitrous oxide in heart tissue is first established by *in vitro* experiments, and with these data it is possible to calculate the blood flow through the coronary system. Simultaneous determinations made with the direct and the indirect (nitrous oxide) methods in dogs have given satisfactory results.[1] The nitrous oxide method has been applied in normal human subjects, although the procedure is not an easy one. The coronary blood flow has been found to be 65 cc./100 gm. of heart tissue per minute. This is 7 to 10 per cent of the total cardiac output per minute.[1]

[1] Eckenhoff, J. E., J. H. Hafkenschiel, M. H. Harmel, W. T. Goodale, M. Lubin, R. J. Bing, and S. S. Kety, *Am. J. Physiol.*, **152,** 356, 1948; Gregg, D. E., F. H. Longino, P. A. Green, and L. J. Czerwonka, *Circulation*, **3,** 89, 1951.

Coronary occlusion. The occlusion of a main branch of a coronary artery produces a serious disturbance in the functioning of the heart and is frequently fatal. Coronary occlusion is becoming an increasingly frequent cause of sickness and death and therefore occupies an ever-larger place in human pathology. It produces the dramatic syndrome known as angina pectoris (see page 161).
Fig. 82. Coronary pulse and aortic pressure in the dog. Upper tracing: sphygmographic record of the anterior descending branch of the left coronary artery. Lower tracing: pressure pulse of the aorta (Wiggers' manometer). Note that both curves are identical and can be superimposed. Time in 0.02 sec. (*Braun Menéndez and Orías.*)

In an anesthetized dog, with the chest opened under artificial respiration, if one of the principal coronary arteries (right or left circumflex, or descendens anterior) is ligated, the most prominent disturbances observed affect (*a*) the rhythm of the heart; (*b*) its dynamics; (*c*) its action currents.

The changes in cardiac rhythm are conspicuous. The most frequent nonspecific disturbance in rhythm is the appearance of premature contractions, nearly always of ventricular origin. They begin 5 to 7 min. after the occlusion, at first occasionally, and then in more or less prolonged series. When extrasystoles appear, ventricular fibrillation is imminent and if it occurs the dog dies. If it does not occur, the premature beats tend to diminish in frequency and after 15 or 20 min. only occasional ones are observed which soon disappear completely. Extrasystoles may arise in ectopic foci situated in the ischemic area,

[1] Bing, R. J., *et al.*, *Am. Heart J.*, **38,** 1, 1949.

or they may be due to local disturbances in conductivity which make a reentrance of the normal impulse possible.

Ventricular fibrillation is a frequent result of experimental coronary occlusion; it has occurred in 75 per cent of the experiments in dogs in which the anterior descending branch was ligated. Sometimes it suddenly puts an end to the activity of a heart that was beating vigorously and maintaining good circulatory conditions in spite of the infarct. In other experiments fibrillation is the final stage of a hypodynamic heart that is beating very feebly. It is always preceded by premature contractions.

Ventricular fibrillation following coronary occlusion is probably due to changed conditions of excitability and conductivity affecting the ischemic area. Furthermore, the cardiac fibers in the infarcted area are not all damaged to the same extent; therefore there are also differences in excitability and conductivity within the necrosed area. Ischemia alone, if it affects the whole heart uniformly, does not cause fibrillation, as is seen in a heart separated from the body and left without any circulation through its vessels; it simply ceases to beat and remains in diastolic relaxation.

Hemodynamic disturbances following experimental occlusion of a main artery or branch of the coronary arteries are not so evident on direct inspection as the disturbances in rhythm, but they have a marked effect on the circulation. They can be observed by recording with optical manometers the intraventricular and aortic pressures; their severity can thus be measured and the compensatory reactions, when they occur, can also be followed.[1]

If the branch occluded is important because of the amount of heart tissue it nourishes, in the majority of cases the heartbeat commences to weaken progressively, immediately after the artery has been tied. Intraventricular and aortic pressures diminish, ventricular systole is shortened, especially the ejection phase, and the

Fig. 83. Coronary occlusion and adequate compensatory reaction. Aortic pressure, left intraventricular pressure, ECG (lead II). *A*, before ligation of the anterior descending branch of the left coronary artery in a dog; *B* to *F*, at different intervals after ligation. Discussion in text (*Orías, O., Am. J. Physiol., vol. 100, p. 629, 1932.*)

[1] Orías, O., *Am. J. Physiol.*, **100**, 629, 1932; Braun Menéndez, E., and O. Orías, *Rev. Soc. argent. de biol.*, **10**, 14, 1934; Maldonado-Allende, I., and O. Orías, *Rev. Soc. argent. de biol.*, **12**, 279, 1936.

initial ventricular tension increases (Fig. 83, *B* and *C*). The subsequent events vary in different cases. In some of them, after a few minutes, the aortic and intraventricular pressures gradually recover the normal level and the ejection phase lengthens, so that the duration of systole is restored and the contour of the pressure curves appears the same, or almost the same, as in the beats preceding occlusion (Fig. 83, *D*, *E*, and *F*). The increase in initial ventricular tension determines the more vigorous contraction of the myocardial fibers not submitted to ischemia (Starling's law of the heart) (Fig. 84). A compensated hypodynamic reaction has occurred. If compensation is complete, as far as the dynamics of the heart is concerned, and ventricular fibrillation has not occurred, the heart continues to function efficiently for a long time, and the animal survives.

If the area subjected to ischemia is too large, or if the other parts of the myocardium are already damaged, hypodynamia becomes progressively more marked, in spite of the increased initial ventricular tension (Fig. 85). On direct examination, the ventricles are seen to be dilated, and there is pronounced stasis in the auricles and large veins. After a short time ventricular fibrillation puts an end to the activity of a heart already incapable of maintaining the circulation. This sequence of events is observed in cases of uncompensated progressive hypodynamia.

In a small number of cases overcompensation may occur. Intraventricular and aortic pressures rise above the level previous to the occlusion, and the duration of systole is prolonged; there is also an increase in initial ventricular tension.
FIG. 84. Diagram to explain the response to sudden coronary occlusion. The upper curves represent the algebraic sum of the lower curves. Each one of the latter represents the contraction of a myocardial unit. Only six have been drawn. The curve *A* is the sum of the six curves below it. *B* is the sum of only five; the unit represented by the small curve in dotted line is supposed not to have responded (hypodynamic contraction). *C* is the sum of the six curves below it; it is of shorter duration because the unit represented by the thick-line curve is supposed to have been modified by ischemia (abbreviated systole). *D* is approximately the same as *A* but is the sum of only five unit curves, which are higher than those under *A*, *B*, and *C* (adequate compensatory reaction). (*Orías, 1932.*)

These experiments show that a myocardial infarct cannot be diagnosed by the changes in arterial blood pressure. A normal, or even a high, blood pressure is not incompatible with the existence of necrotic foci in the myocardium

Disturbances in the action currents of the heart caused by coronary occlusion are revealed principally by changes in the ST segment of the ECG, which after occlusion is usually above or below the isoelectric level, and in the T wave, which may appear deformed or reversed. These changes are typical, within certain limits, for the occlusion of each one of the arterial branches, but they are not apparent in all the leads. The location of the infarcted area conditions the type of change in the ECG. The extrinsic innervation of the heart has no influence on the variations in the ECG. Precordial leads are especially useful for discovering the electrocardiographic changes caused by coronary occlusion. These changes appear within the first two minutes after the vessel has been tied, and they disappear if the ligature is removed a few minutes later (Fig. 86). Venous occlusion alone does not produce them.

Changes in the ECG are the most important signs for the diagnosis of myocardial infarction

and for following its course in man. In some cases these changes even permit the localization of the infarct. Figure 87 reproduces the ECG of a patient with coronary occlusion; in this case there was also auricular fibrillation.

have found that oxygen consumption of the human heart averages 7.8 cc./100 gm. of cardiac tissue per minute.

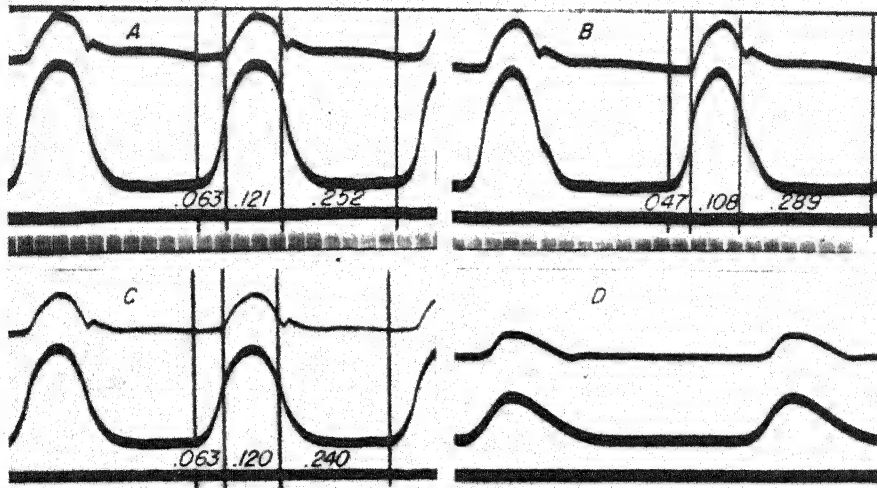
The oxygen content of coronary venous blood in man and in the dog is considerably less than


FIG. 85. Coronary occlusion. Hypodynamic uncompensated response. *A*, aortic and left intraventricular pressure before ligation of the anterior descending branch in a dog. *B*, *C*, and *D* were taken after occlusion of the artery; note the progressive decrease in the strength of the contraction. (*Orías, 1932.*)

that of the mixed blood in the right ventricle. A low oxygen concentration in the sample of blood collected, which can be seen by the dark color of the blood, is a sign that the catheter is rightly placed in the coronary sinus. Bing *et al.*[1] found 11.6 to 15.6 volumes of oxygen per 100 cc. in the blood of the right ventricle, and only 3.9 to 6.9 volumes per 100 cc. in coronary sinus blood of the same subjects. Cardiac tissues, therefore, remove relatively more oxygen (12 volumes per 100 cc., according to Bing *et al.*) than any other tissue in the body. Oxygen consumption per unit weight of cardiac tissue is normal in patients with arterial hypertension.

These determinations have been made in resting subjects. In experiments made on intact animals or with isolated hearts it has been proved that oxygen consumption increases with the work of the heart. Adrenaline also stimulates considerably cardiac oxygen consumption.

THE METABOLISM OF THE HEART

Energy for the contraction of the heart muscle is ultimately derived from oxidation processes which entail the consumption of oxygen and production of CO_2. The total metabolism of the heart can be measured by determining the oxygen consumption or the production of CO_2, but it is also important to know the nature of the oxidized substances and the mechanism of their oxidation. Energy can also be obtained from enzymatic chemical reactions when there is no oxygen available. Unfortunately little is known about these metabolic processes. A thorough knowledge of them would undoubtedly be of great importance in medical practice. Only a brief summary of the better known aspects of cardiac metabolism will be given here.

Oxygen consumption. Oxygen consumption can be measured by determining the difference in the oxygen percentage of arterial and venous blood in the coronary system, and the amount of blood that passes through the heart in unit time. This method has been applied in man, using an intracardiac catheter, the tip of which is introduced into the coronary sinus, but this procedure is by no means easy. Bing and his associates[1]

Heart-lung preparation.[2] Important data on cardiac metabolism can be obtained from the heart-lung preparation. The oxygen consumption of the preparation is the sum of the oxygen

[1] BING, R. J., *et al.*, *Am. Heart J.*, **38**, 1, 1949.

[1] *Ibid.*

[2] STARLING, E. H., *et al.*, *J. Physiol.*, **40**, 285, 1910; **44**, 206, 1912; **48**, 357, 1914.

consumption of the heart and of the lungs. The oxygen consumed by the lungs can be determined by running a control; by deducting it from the total oxygen consumption, the figure corresponding to the heart will be obtained. The heart-lung preparation has also been used to obtain information concerning the substances used as fuel by the heart.

The pulmonary circuit can also be replaced by an artificial oxygenator[1] circuit, in order to avoid the complicating influence of the metabolic processes of the lungs. The heart-lung and heart-oxygenator preparations have the advantage over simple perfusion of the isolated heart of making the heart perform work in conditions more similar to normal.

The fuel used by the heart. Only incomplete data have so far been obtained on the substances used as fuel by the heart. The usual procedure consists in measuring the amount removed from the blood circulating in a heart-lung preparation, or better still in a heart-oxygenator preparation, of the substance studied. Perfusion of the isolated heart with blood, or with a fluid in which the concentration of the substance is known, may also be used in these studies. The determination of the respiratory quotient (ratio of CO_2 produced to O_2 consumed) of the isolated heart, or of the heart-lung preparation, also gives information on the nature of the substances burned.

A well-established fact in cardiac metabolism is the utilization of large amounts of lactic acid, which seems to be the glucidic substance used preferentially to all others by the heart. In ordinary conditions, when there is a good supply of oxygen there is little consumption of glucose, but there is a considerable consumption of lactate. The heart of a dog in a heart-oxygenator preparation consumes 70 mg. of glucose and 200 mg. of lactate per 100 gm. per hr. When the work of the heart increases, the consumption of both these substances also increases. A decrease in the supply of either increases the consumption of the other. The lactic acid used by the heart has its origin in the process of glycolysis that normally takes place in the blood; this process is greatly activated when the blood passes through the lung. Lactic acid produced in the contraction of skeletal muscle and diffused into the blood is also a source of energy for the myocardium.

Note the progressive disturbance in the ECG, and complete recovery after the circulation has been restored. Time in 0.2 sec. (*García del Río and Orías, Rev. Soc. argent de biol., vol. 10, p. 148, 1934.*)

If the glucose and lactate in the blood are exhausted, the contraction of the heart is considerably weakened and the glycogen content of the myocardium diminishes. If either glucose or lactate is again added to the blood, the heartbeats recover their vigor, lactate being more efficient than glucose. On the other hand myocardial glycogen is restored by adding glucose to the blood, but not by adding lactate. Monoiodoacetic acid, which rapidly paralyzes skeletal muscle, does not modify cardiac activity if there is a sufficient oxygen supply.

When there is an insufficient oxygen supply the nutritive processes of the heart undergo a marked change: the myocardium no longer utilizes lactate, but discharges it into the blood, and monoiodoacetic acid rapidly stops the heartbeat. The metabolism of the heart muscle in anoxia thus resembles the metabolism of skeletal muscle.

The following interpretation seems to cover the facts so far known: energy for the contraction of the heart fibers is provided directly or indirectly by the disintegration of phosphocreatine; energy for the resynthesis of phosphocreatine is provided by the oxidation of lactate. In conditions of anoxia, energy for the resynthesis of phosphocreatine is provided by the disintegration of glycogen into lactic acid (as in skeletal muscle).[1]

The heart can utilize pyruvic acid,[2] which is chemically a close relative of lactic acid. It is also supposed to oxidize fats, as the respiratory quotient of the heart deprived of glucose and lactate is 0.7 (RQ of fat oxidation). After a heart-lung preparation has been functioning for some time, the fat content of the heart diminishes. When β-hydroxybutyric acid (one of the intermediate substances in the metabolism of fat) is added to the heart-lung preparation, it is removed from the blood.

There is not much information on the protein metabolism of the heart; but the myocardium does not seem to make direct use of amino acids. Glycine added to the blood circulating in a heart-lung preparation increases the formation of creatine.

Vitamin B_1 (thiamine) plays an important part in cardiac metabolism. Serious and even fatal disturbances in the heart have been ob-

FIG. 87. ECG of a case of coronary occlusion in man. T starts at S in lead I and from the descending limb of R in leads II and III. This type of record is interpreted as corresponding to ischemia of the base and posterior wall of the ventricles (occlusion of the right coronary artery). Auricular fibrillation is indicated by the absence of P, the fine oscillations between the ventricular complexes, and the irregular intervals between these complexes. (*Courtesy of Dr. R. A. Brandán.*)

served in the course of B_1 avitaminosis[1] (see Chap. 49).

The marked changes observed in the functions of the heart in both hyperthyroidism and hypothyroidism clearly show the importance of the internal secretion of the thyroid in normal cardiac metabolism. Adrenaline definitely increases the oxygen consumption of the heart. Little is known about the influence of other internal secretions on cardiac metabolism.

THE WORK OF THE HEART

Energy set free in the course of cardiac metabolic processes is used in part to perform work, but the greater part of this energy is given off as heat. About three-quarters of the total energy set free is lost as heat.

The work of the heart consists in

1. Ejecting into the arteries a certain amount of blood against the resistance of the blood already in the aorta and pulmonary artery. In these arteries there is a certain pressure maintained by the elastic reaction of the partially distended arterial walls.
2. Imparting velocity to the blood ejected so that it will circulate.

The work performed by each ventricle at every beat can be expressed as follows:

$$W = QR + \frac{wv^2}{2g}$$

where W is work, Q is the amount of blood ejected at each systole in cubic centimeters, R is the mean arterial pressure in meters of water (pressure in centimeters of mercury multiplied by 13.6, which is the specific weight of Hg) at the level of the aorta or pulmonary artery, w is the weight of the blood ejected at each systole, v is the velocity of the blood stream in the aorta or pulmonary artery, and g is the gravity constant, *i.e.*, 9.81.

QR represents the work necessary to eject the blood against the arterial resistance, and $wv^2/2g$ the kinetic energy necessary to impart velocity to the column of blood. The result is expressed in gram-meters; one gram-meter is the work performed in raising 1 gm. a height of 1 m.

All data necessary for the calculation of the work performed by the heart can be obtained in man by methods that are in common use. Thus Q is given by the minute volume and the heart rate; R is determined by measuring the arterial blood pressure by any standard method if the resistance in the aorta has to be known, or by transcardiac catheterization in the case of resistance in the pulmonary artery. The kinetic component is calculated as follows: The velocity of the blood is directly proportional to the systolic discharge Q and inversely proportional to the area of the cross section of the aorta, or the pulmonary artery, and the duration of the ejection phase T. With these data the following formula for the kinetic energy has been deduced,[1] in which K is a constant and A the area of the cross section of the aorta (or pulmonary artery).

$$\text{Kinetic energy} = \frac{Q^3}{A^2 \times T^2} = K$$

In man the necessary data are obtained by intracardiac catheterization and angiocardiography.

In six normal, resting subjects the following figures, in gram-meters per beat, were obtained: potential energy for the right ventricle, from 8.42 to 19.70; for the left ventricle, 91.0 to 190.0; kinetic energy, for the right ventricle, 0.31 to 1.30; for the left ventricle, 0.46 to 3.90.

When the subject is resting, kinetic energy is only a small fraction of the total energy developed by the heart, but it increases in importance (up to 25 per cent of the total energy) during physical exercise.

Efficiency of the heart. The efficiency of a motor is the ratio between the energy converted into work and the total energy.

The efficiency of the heart can be calculated, approximately, not only in animals, but also in man.[2] The work of the heart is measured, and the total energy developed is calculated from the oxygen consumption of the heart, determined by the methods described in preceding paragraphs.

The energy cost is obtained by multiplying the oxygen consumption by its energy equivalent. If the RQ (respiratory quotient; see Chap. 40) for the heart is considered to be 0.82, the energy equivalent of oxygen would be 2,059 kg.-m. per liter. Oxygen consumption is usually calculated per 100 gm. of cardiac tissue, but the actual weight of the subject's left ventricle can be obtained from special anatomical tables; thus the total oxygen consumption for the ventricle can be calculated. The results are probably accurate only within ±15 per cent. The effi-

[2] Bing, *et al.*, *loc. cit.*

ciency of the heart is given by the ratio

$$\frac{\text{Cardiac work}}{\text{Total energy cost}} \times 100$$

Bing and his associates,[1] applying these methods in normal men, found the efficiency to be 19.0 to 24.5 per cent, and in cases of congestive heart failure only 13 to 17 per cent.

THE OUTPUT OF THE HEART. THE MINUTE VOLUME

From many points of view it is important to know the output of the heart per minute.

Fick's principle.[2] The minute volume can be calculated by means of Fick's method; the oxygen intake by the lungs during 1 min. is measured, and the oxygen concentration in arterial blood and in the venous blood of the right ventricle is determined. The amount of blood in which the oxygen has been absorbed is easily calculated; this is the amount of blood passing through the lung in 1 min., *i.e.*, the minute output of the right ventricle. The left ventricle ejects the same amount as the right ventricle.

For example, a subject absorbs 248 cc. O_2 in 1 min. and the arterial blood has 45 cc. more oxygen per liter than the venous blood; therefore

$$\frac{1{,}000}{45} = \frac{x}{248}$$

$$x = \frac{248 \times 1{,}000}{45} = 5{,}511 \text{ cc.}$$

The right ventricle in this case has ejected 5,511 cc. in 1 min., and the left ventricle has ejected the same amount. Dividing this by the heart rate, the average systolic discharge is obtained.

The minute volume can be calculated in the same way by measuring the elimination of CO_2 and the arteriovenous difference in CO_2 concentration.

Oxygen or CO_2 concentration must be determined in the blood of the right auricle or ventricle, because this is blood entering the lung. Venous blood from different territories may differ considerably in its O_2 or CO_2 concentration, because of differences in the activity of the tissues. Arterial blood, on the other hand, may be taken from any artery, because it has the same composition in all the arteries.

[1] *Ibid.*

[2] Fick, A., *Sitzungsb. d. physik.-med. ges. sch. z. Würzburg*, p. 16, 1870.

Determination of the minute volume in man. Until rather recently it was customary to resort to indirect methods to determine the minute output of the heart in human subjects. Since the systematic researches of Cournand and his associates,[1] however, the *direct application of Fick's principle* is becoming more and more the procedure of choice. Venous blood is drawn from either the right auricle or the right ventricle by means of a catheter introduced into the heart chambers through one of the veins of the arm. Arterial blood is obtained by puncture of the radial or any other superficial artery. The subject's oxygen consumption is determined by a standard method (see Chap. 40). Samples of blood must be drawn under paraffin while the oxygen consumption is being determined.

There are other indirect methods for measuring the minute volume which can be applied in man. In the acetylene[2] and nitrous oxide[3] methods the subject breathes the gas. The minute volume is calculated from the amount of gas taken up by the body and its concentration in the blood. In other methods the minute volume is calculated from the distribution in the blood of special dyes.[4] All these methods require rather elaborate techniques and are not exempt from errors.

Intracardiac catheterization. Forssmann[5] was the first to apply venous catheterization of the heart in man; after studying the technique in the cadaver, he first performed it on himself. Other investigators occasionally made use of this method,[6] but the credit for systematic use of venous catheterization of the heart is due to Cournand and his collaborators in the United States, and to McMichael and his collaborators in England.[7]

The skin over a vein in the arm is anesthetized and

cleaned thoroughly, and a flexible ureteral catheter (gauge 12) is introduced into the vein. The catheter is slightly bent at 6 to 8 cm. from the end, as this facilitates its entrance into the auricle. If the catheter is opaque to x-rays, its progress can be followed and its tip accurately guided. The injection of a small quantity of sterilized sodium iodide solution, which is also opaque to x-rays, permits the visual control of the position of the catheter, which can be passed to the ventricle if it is desirable to do so. The catheter is flushed with sterilized saline solution and is then connected with a flask containing heparin in saline. A manometric tube graduated in centimeters gives the pressure in the system. Sterile saline is passed continuously through the catheter at the rate of 50 cc. per hr., except when samples of blood are drawn. Not only is the position of the end of the catheter controlled by x-rays; the nature of the blood drawn and the type of the pressure waves registered by a suitable manometer connected to the catheter also give valuable information for this purpose. The cardiac rate and rhythm should be followed in the ECG throughout the procedure. The repeated appearance of extrasystoles is a sign of undesirable irritation of the internal surface of the heart. The nature of an extrasystole will also give information on the position of the tip of the catheter. An already wide experience has proved that this method is usually well tolerated by the subjects submitted to it, but it must not be forgotten that there is a certain risk of thrombosis and ventricular fibrillation.

This method was originally used for intracardiac exploration, but it has since been applied to the collection of blood from deeply situated vessels, *e.g.*, the coronary sinus, the hepatic or renal veins (the catheter is passed through the auricle into the inferior vena cava), and the pulmonary artery or its branches (through the right auricle and ventricle).

The left cavities of the heart have been explored by the introduction of the catheter into the ulnar artery. This is not as easy as venous catheterization, owing to the high pressure in the arteries and the obstacle represented by the aortic valves.[1]

Normal minute volume in man. The average minute volume of normal subjects in basal conditions is 5.4 liters/min., when it is determined by the application of Fick's principle. Different workers have obtained results that are generally in accordance with this average. The minute volume per square meter of body surface is 3.1 liters; this is known as the *cardiac index*.

When the subject stands up, the minute volume diminishes (from 5.3 liters lying down to 4 liters standing up, according to McMichael and Sharpey-Schäfer[1]). Exercise increases the minute volume in proportion to the amount of exercise, up to 15 and 20 liters per min.
FIG. 88. Normal ballistocardiogram. *H*, apex beat; *I*, ballistic recoil during the ejection phase; *J*, impact of blood on the large vessels; *K*, impact of blood on peripheral resistance. The significance of the other waves is not yet clear. (*Sharr, I., and H. A. Schroeder, J. Clin. Investigation, vol. 19, p. 437, 1940.*)

The minute volume is the result of the systolic discharge multiplied by the heart rate. Factors that modify the minute volume will be considered in detail when discussing the importance of the minute volume in maintaining the arterial blood pressure.

Ballistocardiography. If a person lies on a special platform adequately mounted on springs, the platform oscillates synchronously with the heartbeats. The movements are presumably due to the ballistic recoil of the heart during the ejection phase and to the impact of the blood against the aortic arch. The movements of the platform can be amplified and recorded (Fig. 88). The records are called "ballistocardiograms," and by applying certain mathematical formulas it is possible, according to the proponents, to calculate from them the output of the heart.[2] The aspect of the waves recorded in the ballistocardiogram is studied for diagnostic purposes, because although there are no typical curves for the different disturbances in cardiac function, certain alterations in the strength and form of systolic ejection may provoke changes in these waves. A diagnostic conclusion cannot, however, be supported by the ballistocardiogram alone.

CHAPTER 19

Circulation in the Arteries

THE ARTERIES ARE tubes with elastic and muscular walls; they carry the blood to all the organs and tissues of the body. Their structure changes as their distance from the heart increases. The principal change concerns the relative importance of the elastic and muscular coats. Whereas the aorta is almost entirely made up of the elastic tissue, the small arteries and arterioles have a thick muscular layer. These structural differences assure a greater functional efficiency of the arteries in the several parts of the circulatory system.

The walls of the large arteries have great strength and elasticity, and therefore they can resist the high pressure to which they are submitted. Moreover during systole they store part of the systolic energy by converting it into tension, which is reconverted into kinetic energy during diastole. In small arteries, contraction and relaxation of the muscular coat are under the control of nervous and humoral factors, which regulate the inflow of blood to the different tissues according to their physiologic needs.

The aorta, because of its elastic walls, acts as a compression chamber; it absorbs and damps the sudden systolic impulse and sends blood to the small arteries at a more uniform pressure, speed, and rate.

There is still some debate as to whether the contraction of the arterial muscle layer contributes to propel the blood. Some authorities[1] believe this is so, but undoubtedly the main force that makes the blood circulate is the contraction of the heart. The contribution of the arterial muscles, if it exists, must be of very little importance. On the other hand the arteriolar muscles are an important factor in the maintenance and regulation of arterial blood pressure and in the regulation of the blood flow through local territories.

[1] HÜRTHLE, K., *Pflüger's Arch. f. d. ges. Physiol.*, **236**, 385, 1935.

Angiocardiography.[1] The arteries and other blood vessels and the cavities of the heart can be made opaque to x-rays by rapidly injecting them with a concentrated solution of a substance which is opaque to x-rays and is well tolerated by the organism, *e.g.*, a compound of iodine, such as 70 per cent diodrast. Several x-ray films (six or more) are taken at short intervals, which give accurate information on the diameter of the blood vessel, its permeability, etc. The aorta can be visualized by injecting the contrast substance into one of the carotid arteries, directing the needle toward the heart (retrograde aortography).[2]

THE VELOCITY OF BLOOD FLOW IN THE ARTERIES

The velocity of the blood flow varies inversely with the cross-sectional area of the vascular bed in which it circulates. This area increases progressively as the arteries ramify and the distance from the heart increases. The cross-sectional area of each branch is smaller, but the sum of the cross-sectional areas of the branches is always greater than that of the parent vessel. The velocity of the blood flow therefore diminishes progressively as the distance from the heart increases. The ratio of velocity to cross-sectional area is expressed as follows:

$$V = \frac{Q}{A} = \frac{Q}{\pi r^2}$$

where V is velocity, Q is the blood flow in unit time, and A is the cross-sectional area—or πr^2 if this is circular, r being the radius of the circle (half the diameter of the vessel).

[1] SUSMAN, M. L., and A. GRISHMAN, in Dock and Snapper's "Advances in Internal Medicine," Interscience Publishers, Inc., New York, 1947.

[2] PEREIRAS, R., and A. CASTELLANOS, *Radiology*, **53**, 859, 1949.

The velocity of the blood varies at different moments of the cardiac cycle and is greater in the center of the blood stream than in the periphery; therefore the mean velocity is the one generally considered. The activity of the heart causes a velocity pulse in the same way as it creates a pressure pulse. Velocity is at a maximum during the ejection phase of ventricular systole and at a minimum at the end of diastole, except in the blood vessels of the cardiac coronary system. The blood flow never stops completely but only slows down during diastole. The oscillations in velocity caused by the systolic ejection are damped as the distance from the heart increases and the diameter of the arteries decreases.

The differences in velocity between the center and the periphery of the blood flow are due to friction of the blood against the arterial walls and between the different concentric layers that form the blood stream itself. The greatest friction exists between the arterial wall and the most peripheral layer of blood; friction between the blood layers diminishes progressively from the periphery to the center of the stream. Therefore velocity is at a maximum in the center and diminishes progressively toward the periphery. This type of flow is observed in homogeneous fluids, and blood is not homogeneous, as it is made up of cells and plasma. The blood cells in circulating blood form columns in the center of the stream, and plasma circulates preferentially in the periphery. The greater viscosity of the blood cells diminishes the difference in velocity between the center and the periphery, which would be greater in a homogeneous fluid.
Fig. 89. Volkmann's hemodromometer.

Fig. 90. Ludwig's stromuhr.

Determination of the blood flow and its velocity. There are direct and indirect methods for determining the blood flow, *i.e.*, the amount of blood passing through a vessel in unit time, and its velocity. In the direct methods an instrument must be inserted into the blood vessel. Volkmann's hemodromometer was one of the first instruments used for the direct determination of the speed of blood flow and Ludwig's stromuhr for the direct measurement of flow and subsequent calculation of its velocity.

Volkmann's hemodromometer[1] (Fig. 89) consists of a U-shaped glass tube filled with saline solution. The time taken by the blood to fill the tube,

[1] Volkmann, A. W., "Die Hemodinamik," Leipzig, 1850.

displacing the saline solution, is measured with a chronometer; thus the speed of flow can be determined. The inertia of the saline in the tube introduces a certain error into this determination.

Ludwig's stromuhr[1] (Fig. 90) measures the amount of blood that passes through an artery in unit time. To calculate the speed of flow, the cross-sectional area of the artery must also be known.

Registration of the blood flow and its velocity (hemodromography). Indirect methods permit continuous registration of the speed of blood flow by means of instruments called hemodromographs. Oscillations in velocity can thus be continuously recorded and correlated with other phenomena occurring at the same time. If the instruments are calibrated, the blood flow can also be recorded.

Rein's stromuhr[2] registers the speed of flow by an indirect method, which does not require the insertion of an instrument into an artery. The artery is warmed at a certain place by means of diathermy (high-frequency electric waves), and the temperature of the blood is recorded by a thermocouple at a certain distance downstream from the spot warmed. The temperature of the blood will rise as the velocity of flow decreases; the instrument is calibrated so that temperature corresponds to speed of flow.

The mean rate of blood flow through a particular blood vessel can be registered by a recording rotameter[3] (Fig. 91). The cannulas *A* and *B* are inserted into the proximal and distal ends of the blood vessel. A metal float (*D*) rises more or less according to the amount and speed of blood flow. Its position provokes changes in an electromagnetic circuit (*C*), and these changes are registered by a recording galvanometer. The blood must be prevented from clotting by heparin or another anticoagulant.

Changes in the velocity of blood flow. The blood flows in the arteries at a greater speed during systole than during diastole. In the common carotid artery the speed reaches 500 mm. per sec. during systole and slows down to 300 mm. per sec. during diastole. In resting human subjects, with data obtained by intracardiac catheterization, angiocardiography, and other procedures, the mean velocity of flow in the aorta has been found to vary in different individuals between 21.3 and 87.4 cm./sec., and from 33.1 to 63.5 cm./sec. in the pulmonary artery.[1]
FIG. 91. Diagram of recording rotameter. *A*, connection with the proximal end of the blood vessel; *B*, connection with the distal end of the blood vessel; *C*, electromagnetic circuit; *D*, metal float, which on changing its position provokes changes in *C* transmitted by the cables *E* to a recording galvanometer; *F*, rubber stopper for cleaning and filling the instrument. (*After Shipley, R. E., and C. Wilson, Proc. Soc. Exper. Biol. & Med., vol. 78, p. 724, 1951.*)

Local changes in the diameter of the arteries can cause local variation in the velocity of the blood flow. Vasodilatation increases the velocity of the flow and vasoconstriction diminishes it.

THE BLOOD PRESSURE IN THE ARTERIES

The Reverend Stephen Hales, in 1732, gave the first demonstration that the blood in the arteries flows under pressure.[2] He described his experiment in the following words: "In December I caused a mare to be tied down alive on her back. Having laid open the left crural Artery

[2] Quoted by C. Lovatt-Evans in E. H. STARLING, "Principles of Human Physiology," 9th ed., J. & A. Churchill, London, 1945.

about three inches from her belly, I inserted into it a brass Pipe, whose bore was one sixth of an inch in diameter; and to that by means of another brass Pipe which was fitly adapted to it, I fixed a glass Tube, of nearly the same diameter, which was nine feet in length: Then untying the ligature on the Artery, the blood rose in the Tube eight feet three inches perpendicular above the level of the left Ventricle of the heart: But it did not attain to its full height at once; it rushed up about half way in an instant, and afterwards gradually at each Pulse, twelve, eight, six, four, two and sometimes one inch: When it was at its full height, it would rise and fall at and after each Pulse two, three, or four inches; and sometimes it would fall twelve or fourteen inches, and have there for a time the same Vibrations up and down at and after each Pulse, as it had when it was at its full height; to which it would rise again, after forty or fifty Pulses."

This experiment can be repeated in any animal. The height of the blood column balances the pressure in the artery.

Terminology. Arterial blood pressure is the force exerted by the blood on the walls of the arteries. The tension of the arterial wall changes with the pressure. The terms "arterial blood pressure" and "arterial tension" are therefore synonymous; the former is the one commonly used, generally in its abbreviated form of "blood pressure."

Poiseuille's law. Poiseuille's law[1] correlates the factors that determine the circulation of fluids in a system of tubes.

Poiseuille's law states that the volume of fluid (Q) passing through a system of tubes in unit time (minute or volume flow) is directly proportional to the difference between the pressure at the entrance to the system and that at its end ($P_1 - P_2$) and to the square of the cross-sectional area of the tube (q^2). It is inversely proportional to the length of the system (l), to the viscosity of the circulating fluid (η), and to a constant (8π); *i.e.*,

$$Q = \frac{(P_1 - P_2) \times q^2}{l \times \eta \times 8\pi}$$

Therefore the pressure difference will be

$$P_1 - P_2 = Q \frac{l \times \eta \times 8\pi}{q^2}$$

[1] Poiseuille, J. M., *Mem. Acad. Sc.*, **9**, 433, 1846.

where $(l \times \eta \times 8\pi)/q^2$ represents the factors conditioning resistance to the circulation of the fluid; it can be conveniently replaced by the letter R. Therefore

$$P_1 - P_2 = QR$$

In the circulatory system P_1 is the aortic pressure, and P_2 the pressure in the right auricle, which can be considered as zero. Therefore $P = QR$, *i.e.*, pressure in the aortic system is directly proportional to the minute volume ejected by the heart and to the peripheral resistance. Any change in these factors will cause a change in pressure in the same direction. If either of these factors is reduced to zero, the blood pressure will also fall to zero.

Factors that modify the minute volume. The minute volume of the heart is conditioned by the systolic discharge and the heart rate. When the systolic discharge remains constant, or diminishes only slightly, an increase in heart rate causes an increase in the minute volume and the arterial blood pressure rises. This occurs in moderate tachycardia, such as follows section of the vagus nerves, injection of atropine, or stimulation of the accelerators (stellate ganglion).

The systolic discharge is determined by several factors, some of which act in the opposite direction to others. The main factors are (*a*) the physiologic condition of the myocardium; (*b*) the venous return; (*c*) the heart rate.

The physiologic condition of the myocardium. This factor is of fundamental importance. If the heart muscle does not contract, or if its contraction is weak or uncoordinated, blood is not ejected into the arteries, or is ejected in insufficient amounts, and the arterial blood pressure falls; when there is no systolic discharge it falls to zero. The capacity of the myocardium to contract is affected by toxic (in some cases medicinal) substances; degenerative processes; anoxia (total, or limited to a restricted area, such as in the case of infarction by coronary occlusion); dystrophia such as that in B_1 avitaminosis; myocardial fatigue, etc.

Venous return. The amount of blood returning to the auricles by the veins is a primary factor conditioning an adequate systolic discharge. If blood does not return to the heart, however good the physiologic condition of the myocardium, it will not be able to pump into the arteries the blood which is not there. Several factors determine the venous return to the auricle. A

hemorrhage, for example, turns from its course a certain amount of blood. The venous return will then diminish; therefore the systolic discharge will be less, and the arterial blood pressure will fall. A similar effect results from general capillary dilatation, which is usually accompanied by increased permeability of the capillary membrane; more fluid passes from the blood plasma to the tissues, and the blood volume diminishes; moreover the velocity of the blood flow is diminished and the blood stagnates in the periphery. Transfusion of blood will have the opposite effect, but it must not be performed too rapidly; otherwise the capacity of adaptation of the myocardium is exceeded, and myogenic dilatation and acute cardiac insufficiency will follow. The flaccidity of the walls of the veins, and the low pressure of the blood circulating in them, make the veins easily collapsible, and even slight external compression will occlude them completely, thus interrupting the blood flow. If this occurs in the large thoracic veins the venous return will be hindered, and as the systolic discharge is diminished, the arterial blood pressure will fall. A decrease in thoracic pressure sufficient to dilate the veins and increase their capacity will have the same effect, because it causes venous stasis. Respiratory variations in intrathoracic pressure alternately produce both these effects on the great veins: compression during expiration, and decompression during inspiration. In the course of normal breathing the respiratory influence on venous circulation is not considerable; but a forced expiration with the glottis closed (Valsalva's experiment) or a forced inspiration in the same condition (Müller's experiment) will hinder the venous return and cause the arterial blood pressure to fall.

The heart rate. Since the heart rate conditions the duration of diastole, it also conditions the filling of the ventricle and the systolic discharge. In the course of intense tachycardia the increase in the number of systoles does not compensate the decrease in systolic discharge due to insufficient filling of the ventricle; therefore the minute volume diminishes and the blood pressure falls.

Factors that modify peripheral resistance. The peripheral resistance (R) is conditioned by several factors, correlated in Poiseuille's law by the expression $R = (l \times \eta \times 8\pi)/q^2$. The length of the system (l) is constant for each individual; the viscosity (η) is also fairly constant; and 8π is by definition a constant; the only variable factor is the cross-sectional area of the vessel (q). Therefore in a given individual, at a certain moment, the peripheral resistance will depend on the diameter of the blood vessels, which is under nervous and humoral control. Resistance is inversely proportional to the square of the cross-sectional area; therefore even a small decrease in the diameter of the arteries will cause a considerable increase in resistance, and therefore in arterial blood pressure.

The arterioles are in a permanent state of constriction, caused by impulses discharged from the vasomotor center. This tonic constriction is essential for a normal blood pressure; if it ceases (by inhibition or cocainization of the vasomotor center, or section of the spinal cord in the upper cervical region) the blood pressure falls below the level necessary to maintain an adequate circulation to all the tissues.

Permanent tonic constriction of the arterioles is governed by nervous and humoral mechanisms which cause changes in the diameter of the arteries, and thus modify the blood pressure. The effects of these factors will be considered in the next chapter.

Compensatory reactions. Arterial blood pressure is maintained at a fairly constant level by a complicated and sensitive mechanism of control. As soon as one of the factors mentioned modifies the cardiac output or peripheral resistance, compensatory reactions are provoked which tend to counteract the primary effect. For this reason marked changes in blood pressure are caused only by the vigorous action of these factors, and the effects, except in extreme cases, are usually transitory, even when the action persists. The different mechanisms which control blood pressure and their coordination will be considered in the next chapter.

QUANTITATIVE EVALUATION OF BLOOD PRESSURE

Hales's experiment, referred to in detail on page 177, was a quantitative determination of blood pressure. Hales's vertical tube acted as a manometer, but the clotting of the blood occurred too rapidly to allow a sufficiently prolonged observation.

Poiseuille's[1] application of the mercury manometer to the quantitative study of arterial blood

[1] POISEUILLE, J. M., "Recherches sur la force du coeur aortique," Paris, 1828.

pressure was an important advance. A mercury manometer is a U-shaped tube with long branches, partly filled with mercury. When both branches of the tube are submitted to the same pressure (*e.g.*, atmospheric pressure) the mercury is at the same level in both branches. If one of the branches is connected with an artery by means of a rubber tube and a cannula (the whole system is filled with anticoagulant fluid) the blood pressure will be transmitted to this branch of the manometer, and the level of mercury will descend in this branch and rise in the other. The difference in the level of the mercury in the branches measures the blood pressure in centimeters of mercury. This apparatus shows that the blood pressure fluctuates continuously without falling below a certain level.

FIG. 92. Ludwig's mercury manometer and kymograph.

Ludwig[1] made another important advance by placing a metal stem, provided with a float at one end, on the surface of the mercury in the open branch of the manometer. At the other end of the stem an indicator was attached so as to register on a kymograph the fluctuating level of the mercury column. This apparatus (Fig. 92), still in common use in physiological laboratories, was the first used to record circulatory phenomena, inaugurating thus the method of graphic registration, which has given such valuable results in medical and physiological research.

[1] LUDWIG, K., *Arch. f. Anat. u. Physiol.*, p. 242, 1847.

The mercury manometer does not reproduce faithfully the fluctuations in arterial blood pressure, because of its great inertia and low natural frequency. The fluctuations in pressure are therefore damped; the high values are less, and the low values greater, than the real ones. If the fluctuations are damped even more, by constricting the tube or rubber connection between the artery and the manometer as Marey proposed, only minute oscillations occur at each heartbeat, and a record of the mean arterial pressure is obtained. This is an important feature in circulation. The mean pressure would be the constant pressure which assures the same volume flow as the pulsating pressure. It could also be defined as the average of the infinite number of pressures existing during the interval considered. A damped mercury manometer gives an objective demonstration of the theoretical mean pressure and a reasonable approximation of its true value, without the need of a complicated mathematical calculation.

Elastic manometers are necessary to obtain a faithful record of the oscillations in arterial blood pressure; the most sensitive and accurate of them resort to optical registration. Wiggers' universal manometer and Hamilton's manometer give excellent results. They must be standardized with a mercury manometer to obtain the values of blood pressure.

The more accurate instruments also show that the pressure in the arteries is fluctuating continuously above a certain level, without ever falling to zero. Fluctuations usually occur above 60 to 70 mm. Hg. They are due to three main causes: cardiac activity, respiration, and vasomotor tone.

Cardiac fluctuations. The most important oscillations in blood pressure, because of their amplitude and medical significance, are those due to ventricular systole and diastole. The pressure rises from between 60 and 70 mm. Hg in diastole to between 110 and 130 mm. Hg at each systole. This sudden increase in pressure is due to the entrance into the aorta of the blood ejected by the ventricle, and is the cause of the arterial pulse. The exact form of this variation

in pressure at each cardiac cycle is shown in Figs. 93 and 94, which reproduce records obtained in human subjects with Hamilton's manometer, and in Fig. 106, a record obtained in the dog with Wiggers' manometer. The differences in the records obtained from different arteries will be discussed when considering the arterial pulse.

Respiratory fluctuations. Breathing causes variations in blood pressure. The maximum pressures observed during the three or four beats corresponding to inspiration are not the same as those in the three or four beats corresponding to expiration. The difference for the same moment of the cardiac cycle is usually of a few millimeters, seldom of 1 cm. (Fig. 93).

A double mechanism causes this respiratory variation in arterial blood pressure. On the one hand there is the functional correlation between the respiratory and cardiovascular centers in the medulla, and on the other the mechanical changes caused by the movements of the thorax. Functional correlation of the centers causes respiratory sinus arrhythmia (see page 145), with tachycardia during inspiration and bradycardia during expiration; therefore arterial blood pressure tends to rise in inspiration and fall in expiration. The mechanical effects of

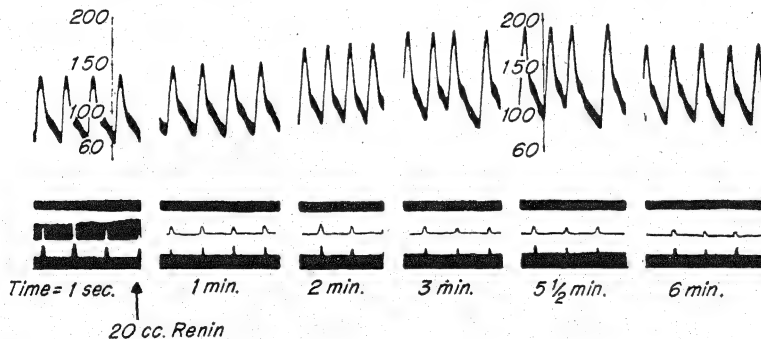
FIG. 93. Record of femoral arterial blood pressure registered with Hamilton's manometer in man. Pressure scale on the left in mm. Hg. *R*, respiratory oscillations. (*Courtesy of Dr. A. Lanari.*)


FIG. 94. Record of femoral arterial pressure in man, obtained with Hamilton's manometer. The arrow marks the injection of a dose of human renin. (*Battro, A., E. Braun Menéndez, A. Lanari, and L. F. Leloir, Rev. Soc. argent. de biol., vol. 16, p. 376, 1940.*)

respiratory movements produce the opposite results. During inspiration intrathoracic pressure falls, the thoracic veins are distended, and the venous return to the heart diminishes; the filling of the heart is reduced and the minute volume also diminishes; therefore the arterial blood pressure tends to fall. In the dog the effects of respiratory arrhythmia predominate (hypertension during inspiration); in man the mechanical effects are predominant (hypertension during expiration).

Vasomotor fluctuations. A third type of variation in blood pressure, much slower than the previous two, can be observed when a record is taken over a certain time. The line joining the peaks of the highest pulse wave in each respiratory cycle shows fluctuations, which have been attributed to variations in the tonic activity of the vasomotor centers.

The three types of fluctuation in arterial blood pressure can be seen in records taken with a mercury manometer, especially the cardiac and respiratory oscillations, but the true values of the pressure are not recorded.

In man the only fluctuations of practical interest are those due to ventricular contraction. It is usual in medical practice to measure the lowest pressure in diastole (diastolic pressure) and the highest in systole (systolic pressure). With the methods in common use other fluctuations can be detected only in special circumstances. The difference between systolic and diastolic pressures is known as the pulse pressure.

MEASUREMENT OF ARTERIAL BLOOD PRESSURE IN MAN

In man, the surgical methods used in animals to study the blood pressure are seldom employed. Direct determination of blood pressure can be made by puncturing an artery (brachial or femoral artery) through the skin, connecting the needle with a mercury manometer when the mean pressure is to be measured, or with a Hamilton manometer when a faithful record of the different oscillations is needed. In this last case the manometer and needle should be connected by a nondistensible but flexible tube (*e.g.*, thin lead tubing). The needle, tube, anticoagulant fluid, etc., should be carefully sterilized, but the whole operation is not difficult and entails no risk to the patient.

In current medical practice blood pressure is measured by methods that cause no inconvenience to the patients. They consist in exerting pressure through the skin and tissues on the artery in which the blood pressure is to be measured, by means of a pneumatic bag, applied to the limb by an inextensible cuff or bandage. An inflating bulb or pump serves to give the desired pressure, which is measured by a manometer. A valve permits gradual escape of the air in the bag, thus lowering the pressure. Mercury manometers are more accurate than aneroid manometers, which must be frequently checked.

Several criteria are used to estimate the external pressure that equalizes the internal pressure. The palpation, auscultatory, and oscillometric methods will be considered. They are known as "sphygmomanometric" methods (σφυγμός, pulse) because they measure the pulse pressure.

Palpation method of Riva-Rocci.[1] The arterial pulse is palpated below the place of compression. The pressure is gradually raised in the armlet until the pulse is no longer felt, and the pressure is read on the manometer. The pressure is raised a little more and then the air is allowed to escape gradually through the valve; when the pulse is again felt, the pressure is read. The average of the two readings is taken as the systolic pressure. The exact external pressure needed to suppress the pulse will be that which equalizes the maximum systolic pressure. With this method it is not possible to measure the diastolic pressure.

Auscultatory method. The sounds occurring simultaneously with the pulsation of the artery are explored below the site of compression. This method proposed by Korotkow is one of the most accurate of the nonsurgical methods, and it serves to measure the systolic and diastolic pressures. Air is pumped into the armlet until it is higher than the pressure in the artery. A stethoscope or a phonendoscope is placed over the brachial artery below the site of compression. As long as the pressure in the armlet is higher than the maximum systolic pressure the artery will be continuously collapsed and as no blood will pass below the compression, no sound will be heard. The pressure is gradually reduced by letting air escape from the armlet, until a soft sound is clearly heard at each heartbeat. The pressure is read on the manometer and then

[1] Riva-Rocci, S., *Gazz. med. di Torino*, **51**, 52, 1896.

the pressure is reduced slightly; the intensity of the sounds increases; the pressure is raised again gradually until the sounds are no longer heard. A second reading is made of the exact pressure at which the sounds disappear. The average of the two readings gives the systolic pressure. Air is gradually let out of the armlet, and as the pressure falls the sounds first reappear and then increase in intensity. The characteristics of the sounds vary from one subject to another, and it is not possible to make a systematic description, which will be valid for all cases, of the changes taking place as decompression progresses. At a definite moment in the process of decompression, the intensity of the sounds diminishes suddenly; this decrease is clear-cut and leaves the observer in no doubt as to when it occurs. The pressure read on the manometer at this moment is the diastolic pressure. If decompression is continued the intensity of the sounds diminishes gradually, and they disappear completely even before the decompression is completed. These changes in intensity have no definite significance. Arterial sounds are due to vibrations of the vascular walls and to the turbulent flow caused by the pressure wave modified by compression of the artery. A more precise explanation cannot yet be given.

Oscillometric method. This method is based on the analysis of the oscillations in the arterial wall (transmitted by the tissues and skin surrounding the artery) when different internal and external pressures act on it. The instruments must therefore have not only a pneumatic armlet and manometer, but also some device to make visible or register the oscillations. Pachon's[1] oscillometer (Fig. 95) is one of the instruments of this type most commonly used in France and other Latin countries.

The oscilloscope in Pachon's instrument (the wall of the aneroid *c*) is always submitted to the same internal and external pressure, whatever the pressure in the system. According to Marey's principle, therefore, it is always in optimum condition to respond with an ample oscillation to any difference between the external and internal pressures. When the connection *f* is open, changes in pressure caused by the pulse wave are transmitted equally to both sides of the capsule, and their effects are annulled. On closing *f* the pulsation is transmitted only to the aneroid, its wall being in optimum conditions for oscillations. The arterial wall, the tissues, and the pneumatic armlet are in a condition similar to the aneroid with respect to the capacity to oscillate. If the pressure in the armlet is constantly above that in the artery, the vessel will be permanently occluded and a small oscillation will be observed at each heartbeat (Fig. 96). These "supramaximal" oscillations are due to the water-hammer effect on the upper edge of the armlet produced by the column of blood in the occluded artery. If the pressure within and without the artery are the same, maximum oscillations will be observed; this is what happens when the external pressure is equivalent to the mean arterial pressure. Finally, when the external pressure is constantly below that in the artery, oscillations will be of

M E l P c b V S f a B

FIG. 95. Diagram of Pachon's oscillometer.

[1] PACHON, M. V., *Compt. rend. Soc. de biol.*, **66**, 733, 776, and 955, 1909.

very small amplitude or will disappear completely; this is what happens when the external pressure is lower than the diastolic pressure.

Pachon's instrument can be adapted to an oscillographic capsule, based on the same principle as the oscilloscope described, which will register the oscillations on a kymograph.

Pe

Decompression

Mn

Mx
FIG. 96. Variations in amplitude of the oscillations of Pachon's oscillometer at different pressures. *Mx*, systolic pressure; *Mn*, diastolic pressure; *Pe*, oscillometric index.

There are several other instruments, oscilloscopes and oscillographs, which serve to measure human blood pressure; they are based on principles similar to those of Pachon's instrument. The main difficulty in all these instruments is that of establishing the exact moment at which a change in amplitude corresponds to one of the pressure values to be measured. Frequently the change in amplitude is not as definite as might be wished.

Oscillometric instruments are also very useful for exploring the arteries when occlusion by disease (*e.g.*, endarteritis obliterans) is suspected. A decrease in the amplitude or the absence of oscillations is a sign of partial or total arterial occlusion.

Accuracy of sphygmomanometric methods.[1] It is now a well-established fact that blood pressure cannot be measured with absolute accuracy by sphygmomanometers. Direct registration of blood pressure by means of intra-arterial manometers has shown that (*a*) even during normal breathing with slight sinus arrhythmia, systolic and diastolic pressure vary several millimeters of mercury from beat to beat, these variations increasing considerably when there is marked arrhythmia or deep breathing; (*b*) determinations of blood pressure in the brachial artery with the auscultatory method give figures 3 to 4 mm. Hg below the true pressure, with an average dispersion of ±8 mm. Hg; (*c*) diastolic pressure taken with the auscultatory method and read at the level when the intensity of the sound diminishes suddenly is more or less 8 mm. below the true value. In normal persons, therefore, an error of ±8 mm. Hg must be allowed for in single determinations. Sphygmomanometric methods, in spite of their shortcomings, are of great value in medical practice.

NORMAL VALUES OF BLOOD PRESSURE IN MAN

An immense number of determinations have been made to establish the normal values of blood pressure in man. Subjects of different sex, age, etc., candidates for life insurance, school children, university students, army recruits, etc., have been examined.

Individual differences are considerable. In groups of the same age, physical constitution, and occupation, one individual will be apparently normal with a systolic pressure of 100 mg. Hg or less, and another equally healthy will have a systolic pressure of 130 mm. Hg or even higher. All intermediate values between these extremes will be found. Average figures, therefore, have only a relative value. Even careful statistical studies in which the standard deviation or probable error is stated, although they are of interest in the general study of blood pressure, are not much help when deciding whether the blood pressure of a certain individual is normal or not.

The only legitimate conclusion is that the

blood pressure of an individual has a statistical probability of being normal. If, on the other hand, a man usually has a blood pressure of 130 mm. Hg when in a healthy condition, and is found to have a pressure of 95 mm. Hg, it must be considered as considerably below normal in his particular case, although statistically it has a certain probability of being normal.

The normal standard of blood pressure for an individual, as for other aspects of his constitution and functions, can be established by examining him in conditions of perfect health. If these data were noted on a health card it would be possible to detect any deviation from the normal as soon as it began.

The blood pressure has been correlated statistically with the age of the individuals. Systolic pressure in mm. Hg is roughly equal to 100 plus the age, except that after 50, figures above 150 mm. are certainly too high. Thus 120 mm. would be the normal blood pressure for a 20-year-old subject; 130 mm. for one 30 years old, etc. Such definite standards have not been established for diastolic pressure. It is usually admitted that diastolic pressure is half the systolic plus 10 to 20 mm. For example, a diastolic pressure of 70 to 80 should correspond to a systolic pressure of 120.

In Córdoba (Argentina) Moisset de Espanés found the following averages in 1,123 university students: systolic pressure, 130 mm. Hg, the extreme cases being 108 and 154; diastolic pressure, 78 mm. Hg, with 61 and 95 as extreme figures. In army recruits in training, many cases were observed with a systolic pressure between 90 and 100 mm. Hg.[1]

Wiggers[2] summarizes as follows the results obtained by several observers: "According to one group of observers the mean pressure values in mm. Hg are approximately 90/65 at three or four years, then increase rather steadily to about 100/70 at ten years, to 110/75 at fourteen years and to 115/75 at sixteen years of age. According to another group of observers the pressures are lower in early childhood, approximately 80/50 at the age of three years. Some believe that only one sudden jump occurs at the approximate age of ten or twelve years, others that another sudden increase is evident near the age of six years. Roughly, the pressures may be said to have increased approximately to 85/55 at six years, to 95/55 at ten years, to 115/65 at fourteen years and to 120/75 at sixteen years of age."

At birth direct measurements have given values of 80/46.

Determinations made with armlets 6 cm. wide give values that are too low. Armlets 12.5 cm. wide give more accurate results.

In old people systolic and diastolic pressures tend to decrease after 65 years of age. This is attributed to a progressively diminishing cardiac efficiency.

After puberty males have higher average blood pressures than females of the same age.

Orientals have lower blood pressure averages than European or American whites.

During sleep, except when dreams disturb normal conditions, systolic pressure falls 15 to 30 mm., and diastolic pressure 5 to 10 mm.

Posture produces changes which vary in different individuals. Physical exercise produces a rapid increase at the beginning and then a slight fall, with stabilization at a level above the resting figure. The type, intensity, and duration of the exercise, and the condition (training, etc.) of the subject have considerable influence on the response of the blood pressure (see Chap. 47).

CHAPTER 20

Vasomotor Activity

SMALL ARTERIES AND arterioles are provided with a thick layer of smooth muscle, which is under nervous control. Contraction and relaxation of this muscular layer determine the diameter of the arteries. Substances in the blood may also modify the diameter of the blood vessels, either by direct action on the arterial muscles or by modifying the activity of the vasomotor centers. All these agents act in a coordinated way, as part of integrative mechanisms that assure the unity and constancy of the organism. They contribute to maintain an adequate arterial blood pressure and to distribute the blood to different regions according to the physiologic needs of the moment.

VASOMOTOR NERVES

Claude Bernard[1] discovered the vasomotor nerves in 1851. He observed that cutting the cervical sympathetic in a rabbit caused dilatation of the arteries in the territory it innervated, clearly visible in the ear on the denervated side.

The vasomotor centers continuously discharge impulses along the sympathetic nerve fibers which keep the arterial muscles in a state of tonic contraction. When the sympathetic is cut, these impulses are interrupted and the arteries and arterioles dilate passively.

Electrical stimulation of the peripheral end of the cut sympathetic produces vasoconstriction (Brown-Séquard, 1852). The blood vessels, which are dilated after the nerve has been cut, contract on stimulation, and only the larger ones appear as thin filaments to the naked eye. There is marked contrast between the vascularization of the two ears, but in the opposite direction to that observed in Claude Bernard's experiment. Arterial constriction persists as long as the nerve is stimulated, and afterward disappears gradually. This experiment also shows that the tonic constriction of the arteries maintained by nerve impulses can be increased by stronger stimulation of the nerve fibers.

[1] BERNARD, C., *Compt. rend. Soc. de biol.*, **40**, 168, 1852.

Claude Bernard[1] also discovered the vasodilator nerves. He observed an increase in the blood flow through the submaxillary salivary glands when the chorda tympani was stimulated.

Stimulation of a nerve can provoke vasoconstriction, vasodilatation, or both. The cervical sympathetic and splanchnic nerves are vasoconstrictor nerves; the splanchnics are the most important of all vasoconstrictor nerves, because of the large territory they innervate and the intensity of their effect. The chorda tympani and the nervi erigentes (pelvic nerves) are vasodilators. Stimulation of the majority of the large nerve trunks may produce either vasoconstriction or vasodilatation, as they carry vasoconstrictor and vasodilator fibers. The origin of these fibers, although complicated, can be determined, as will be demonstrated further on.

Effects of arterial dilatation and constriction. Vasodilatation in an organ causes it to redden, its volume and temperature increase, and the blood flow through it is considerably greater. Any lesion that cuts a blood vessel causes abundant hemorrhage. The increase in blood flow is relatively greater than the increase in the vascular bed; therefore the blood flows more rapidly, especially through the capillaries. The quick passage of the blood gives less time for the exchange of oxygen and CO_2 between the blood and tissues; therefore the arteriovenous difference for both gases diminishes.

Since arterial dilatation causes a decrease in peripheral resistance, the arterial blood pressure

[1] *Ibid.*, **46**, 159, 1858.

falls and the venous pressure rises. The fall in arterial pressure is less marked than the rise in venous pressure, except when arterial dilatation extends to a large vascular territory. In this case venous pressure can also fall because of the stasis caused by the increase in the vascular bed.

wax, or plasticine. The organ must not fill the plethysmograph completely; there must be an air space to allow for its expansion. The air space is connected by means of rubber tubing with a Marey tambour (for registering on a kymograph) or a Frank segment capsule (for optical registration). The changes in volume in the organ will modify the pressure in the air space, and a record called a plethysmogram will be obtained.

V
A
U
FIG. 97. Plethysmograph for registering the volume of the kidney. *A*, renal artery; *V*, renal vein; *U*, ureter.

Vasoconstriction produces the opposite effects.

The best criteria for measuring the degree of vasodilatation or vasoconstriction are (*a*) the changes in volume of the organ and (*b*) the blood flow through the efferent veins. The former is most frequently used, and a plethysmographic record is obtained. It must not be forgotten that changes in volume and blood flow can be produced passively by an increase in the blood pressure, without the active participation of the arterial muscles; blood pressure must, therefore, be recorded simultaneously in all cases.

Plethysmography. This consists in recording the changes in the volume of an organ. The organ is enclosed in a box with rigid walls, the form of which varies according to the organ examined. The instrument is known as a plethysmograph (Fig. 97).

A plethysmograph opens on hinges as if it were the two valves of a clam. The free edges fit closely except at one place, where an orifice leaves a passage for the nerves, vessels, and excretory ducts of the organ; it must be sufficiently ample not to constrict these structures, but not so wide as to leave the inside of the plethysmograph in communication with the outside. The opening is closed with petroleum jelly, wax, or plasticine.

The plethysmograph so far described is used for pediculated organs (such as the kidney); they are also known as "oncometers" (Greek ὄγκος, bulk, and μέτρον, measure). When the volume of a whole limb is to be measured, the limb is introduced into a cylinder (somewhat larger than the limb) open only at one end (Fig. 98). The cardiometer (Fig. 24) described in Chap. 12 is a plethysmograph.

Photoelectric plethysmography consists in transillumination of an organ (preferably with ultraviolet light) and registering, by means of a photoelectric cell, variations in the light passing through the organ.[1]

With a sufficiently sensitive plethysmograph, a rise and fall in volume at each heartbeat will be observed. This pulsation is due to the expansion of the blood vessels produced by the increase in pressure and flow caused by the systolic discharge. In addition to these "cardiac" fluctuations in volume, other much slower changes

[1] Matthes, K., and F. Gross, *Arch. exper. Pathol. u. Pharmakol.*, **191**, 391, 1938.

are observed, which are due to (*a*) changes in arterial blood pressure, which passively modify the expansion of the blood vessels in the organ; (*b*) active modifications in the diameter of the blood vessels, caused by contraction or relaxation of the arterial muscles. A simultaneous blood-pressure record will permit these changes to be attributed to one cause or the other. Figure 99 reproduces a record of arterial blood pressure, obtained with a mercury manometer, and a plethysmogram of a leg of a dog that had received an intravenous injection of adrenaline. The blood pressure rose, and the volume of the leg increased for a short period and afterward decreased. This decrease is due to vasoconstriction; otherwise the rise in blood pressure would produce a passive increase in volume. The increase in blood pressure is due to the increase in peripheral resistance brought about by the constriction of the arteries.

Origin and distribution of vasoconstrictor fibers. Langley's[1] classic experiments on the effects of nicotinization of nerve ganglia demonstrated the distribution and principal connections of vasoconstrictor fibers. Almost all these fibers belong to the thoracolumbar division of the autonomic nervous system. They emerge from the spinal cord in both ventral roots of the twelve thoracic nerves and the two or three upper lumbar nerves. These fibers form part of the white rami that go from the spinal nerves to the ganglia of the homolateral sympathetic chain, where they end synaptically on the ganglion cells. The axons of these neurons (postganglionic fibers) form part of the gray rami going back to the spinal nerves, with which they are distributed to the tissues.

FIG. 98. Plethysmograph for registering the volume of a limb.

Nicotine suppresses the effects of preganglionic stimulation, but postganglionic stimulation continues to produce results. This experiment shows that the fibers are interrupted in the ganglia.

Vasoconstrictor fibers for the head leave the spinal cord in the first four thoracic nerves and join the sympathetic chain. Some have their relay station in the thoracic ganglia and others

[1] LANGLEY, J. N., *J. Physiol.*, **11**, 123, 1890.

in the cervical ganglia. Finally they reach their destination through the periarterial plexuses. These were the fibers discovered by Claude Bernard in the cervical sympathetic.

Vasoconstrictor fibers for the upper limb leave the spinal cord in the fourth to the tenth thoracic nerves.
FIG. 99. Plethysmogram of the leg and arterial blood pressure of a dog injected intravenously (arrow) with adrenaline. The volume of the leg after an initial dilatation diminishes considerably because of vasoconstriction; vasoconstriction causes the rise in blood pressure.

The splanchnic area, which extends to the abdomen and pelvis, receives vasoconstrictor fibers from the last five thoracic and the first two or three lumbar nerves. The majority of these fibers form part of the major and minor splanchnic nerves.

Vasoconstrictor fibers for the lower limb leave the spinal cord in the second and third lumbar nerves.

The thoracic and abdominal walls receive vasoconstrictor fibers from the corresponding spinal segment. There is a strictly homolateral innervation, although there are numerous anastomoses between the blood vessels across the mid-line of the body.[1]

Constrictor fibers for the coronary vessels form part of the vagi nerves, which belong to the cranial division of the parasympathetic.

Origin and distribution of vasodilator fibers. The distribution of vasodilator fibers does not follow such a simple plan as that of the vasoconstrictors. Vasodilator fibers may be classified in three main groups: (*a*) parasympathetic; (*b*) sympathetic; (*c*) the so-called "antidromic" vasodilators.

Parasympathetic vasodilators belong to the cranial and sacral divisions of the parasympathetic. They exert no tonic action, but on stimulation they provoke vasodilatation in the territory they innervate. Among the cranial fibers are those discovered by Claude Bernard in the chorda tympani for the submaxillary salivary gland; these, together with those which emerge from the central nervous system in the seventh nerve, join the major superficial petrosal nerve and end in the sphenopalatine ganglion, whence the postganglionic fibers go to the lachrymal, nasal, and buccal glands. Vasodilator fibers for the tongue leave the seventh nerve and join the lingual nerve. The ninth nerve (glossopharyngeal) sends fibers through the minor superficial pretosal nerve to the parotid gland. The sacral division gives the nervi erigentes to the genital organs.

Sympathetic vasodilators produce, in experimental conditions, less clearly marked effects, because they are masked by the simultaneous stimulation of the predominant vasoconstrictors. For vasodilatation to be evident, the vasoconstrictors must first be paralyzed by an adequate dose of ergotamine.

The effect of sympathetic vasodilators is most clearly seen in the coronary arteries, because here the vasoconstrictors form part of the parasympathetic and not of the sympathetic division of the autonomic nervous system. There are sympathetic vasodilators for the skeletal muscles, the importance of which varies in the different species. There are sympathetic vasodilators in the splanchnic nerves: after the injection of large doses of ergotoxin, stimulation of the splanchnic nerve causes a fall in blood pressure[1] (for details see Burn[2]).

Antidromic vasodilators are exceptional in the organization of the nervous system because they form part of the dorsal roots of the spinal nerves: peripheral stimulation of these nerves provokes a motor effect, *i.e.*, relaxation of the muscles in the arterial walls. This is contrary to the Bell-Magendie law, which states that the ventral roots are motor and the dorsal roots sensory;

[1] GILDING, H. P., *J. Physiol.*, **74**, 34, 1932.

[1] DALE, H. H., *J. Physiol.*, **46**, 294, 1913.
[2] BURN, J. H., *Physiol. Rev.*, **18**, 137, 1938.

they are called antidromic vasodilators because they conduct impulses in the opposite direction to the majority of the fibers traveling in the dorsal root (see Chap. 69, Antidromic Conduction).

Stricker[1] observed that peripheral stimulation of the dorsal roots provoked vasodilatation in
FIG. 100. Stimulation of the peripheral end of the seventh lumbar dorsal root in the dog. From above down: volume of hind leg, arterial blood pressure, signal marking stimulation, and time in seconds. (*Bayliss, W. M., J. Physiol., vol. 26, p 173, 1901.*)

the corresponding cutaneous and visceral territories. This fact was later confirmed by Bayliss[2] (Fig. 100). The origin and nature of the fibers concerned are still uncetains. A widely accepted interpretation is that they are sensory fibers, belonging to the unipolar sensory neurons of the spinal ganglia. Some of the branches arise as sensory (pain) fibers in the skin and tissues; other branches of the same fibers arise in the arterial walls. Stimulation of these fibers, either between the ganglion and the spinal cord or peripherally to the ganglion, spreads throughout the whole neuron and all its branches. It therefore spreads also to those arising in the arteries, where it provokes relaxation of the muscle layer. Antidromic vasodilatation, however, is not a mere experimental curiosity without functional significance; certain cutaneous vascular responses have been explained by the existence of the fibers and their peculiar distribution. For example, mechanical irritation of the skin or the application of mustard oil provokes local cutaneous vasodilatation, but this does not occur if the skin has been anesthetized with cocaine. Nerve conduction is therefore necessary for this type of reaction, which appears to be a reflex; but it is not a true reflex because section of the root, centrally or peripherally to the spinal ganglion, does not suppress the response. A so-called "axon reflex" seems to have been provoked, *i.e.*, mechanical irritation or mustard oil stimulates the cutaneous branches of the axon and the impulses spread to all its branches traveling centrifugally to the artery (antidromic conduction) where they provoke relaxation (Fig. 101).

Herpes zoster, produced by inflammation of the spinal ganglion, has been attributed to this type of mechanism.

Antidromic vasodilatation has also been attributed to the stimulation of motor fibers, which would emerge from the spinal cord in the dorsal instead of in the ventral roots.

Dissociation of the vasomotor effects produced by stimulation of mixed nerves. Usually nerve trunks have vasodilator and vasoconstrictor fibers. According to the nature of the stimulus or the condition of the nerve, the
FIG. 101. Diagram of vasodilatation produced by antidromic impulses. *GC*, dorsal root ganglion cell; *S*, skin; *A*, arteriole. The nervous fiber arises in the skin and in the arteriole. The arrows mark the direction in which the nerve impulses spread when the skin is stimulated, and show how a pseudoreflex can be produced even after the root has been cut.

result of stimulation will be constriction or dilatation. Constriction is usually the predominant effect, and vasodilatation is not easily observed.

Stimulation of the peripheral end of a mixed nerve, immediately after it has been cut, pro-

[1] STRICKER, S., *Wien. Sitzber.*, **74**, 173, 1876.
[2] BAYLISS, W. M., *J. Physiol.* **26**, 173, 1901; **28**, 276, 1902.

duces marked vasoconstriction. Stimulation of the same nerve 4 days after it has been cut has the opposite effect. Constrictor fibers therefore degenerate more rapidly than dilator ones. Vasodilator fibers are also more resistant to cold than the constrictors. Stimulation at rates between 16 and 64 induction shocks per second provokes vasoconstriction; at rates of 1 to 4 shocks per second there is vasodilatation. After injection of ergotamine, which paralyzes the vasoconstrictor fibers, stimulation produces vasodilatation.

Mechanism of vasodilatation and constriction. Vasoconstrictor fibers exert a continuous "tonic" effect. Vasodilatation can be provoked by suppressing this effect (passive vasodilatation) and, in a more intense degree, by stimulation of vasodilator fibers (active vasodilatation). Vasodilator fibers exert no "tonic," permanent action. There is a certain degree of vasoconstriction permanently maintained in all the arteries; vasodilatation is transitory and localized to a definite territory.

Chemical mediators. As in other aspects of visceral innervation, the vasomotor nerves produce their effects by the release of chemical mediators. Vasomotor fibers are cholinergic or adrenergic according to whether they liberate acetylcholine or sympathin.

Not all the vasomotor fibers can as yet be classified as belonging to one or another of these types. Sympathin is liberated by vasoconstrictor fibers, with the exception of those acting on the coronary arteries. These fibers are adrenergic vasoconstrictors and form part of the sympathetic system. Cholinergic vasoconstrictors are exceptional. The vasoconstrictors of the coronary arteries belong to this type; they form part of the parasympathetic system.

Cholinergic vasodilators include

1. All parasympathetic vasodilators (chorda tympani, petrosal nerves, nervi erigentes, etc.).
2. Antidromic vasodilators. These fibers also release histamine, according to Lewis and Marvin.[1]
3. Sympathetic vasodilators of skeletal muscles. These, together with the secretory fibers of the sweat glands, are a notable exception to the general rule that sympathetic postganglionic fibers are adrenergic.

[1] Lewis, T., and H. M. Marvin. *Heart*, **14**, 27, 1927.

Adrenergic vasodilators dilate the coronary arteries; they belong to the sympathetic system.

Summary. Vasoconstrictors, with the exception of those of the coronary arteries, are adrenergic; vasodilators are cholinergic, with the exception of those of the coronary arteries. The effect on the arteries seems to depend more on the nature of the chemical mediator than on the origin of the nerve fibers. For example, a discharge of adrenaline from the adrenals will provoke generalized vasoconstriction, except in the coronary arteries. These arteries will therefore dilate in this condition that demands a greater effort from the heart to overcome the increased peripheral resistance and provide the myocardium with an increased blood flow.

Ergotamine paralyzes adrenergic fibers, and atropine paralyzes cholinergic fibers. Atropine has less effect on the vasodilators than on the cardiac vagal nerves and the secretory fibers of the chorda tympani. Much larger doses are needed to suppress vasodilatation than those needed to suppress cardiac inhibition or salivary secretion.

VASOMOTOR CENTERS

The activity of vasomotor fibers is coordinated by nerve centers. The principal vasomotor center, situated in the medulla, was discovered by Ludwig. There are subsidiary centers in other parts of the central nervous system. The center in the medulla has a permanent vasoconstrictor effect, which is of great importance to the maintenance of the arterial blood pressure. Complete section of the spinal cord just below the medulla produces a fall in blood pressure, which causes a condition of circulatory failure known as shock. This hypotension, with stasis due to widening of the vascular bed, is not permanent. Approximately four hours after the section (during which time the animal is kept alive by artificial respiration because the paths from the respiratory center have been severed) the blood pressure begins to rise and can reach a normal, or approximately normal, level. Recovery is due to an increased activity of the subsidiary spinal centers, which compensate, up to a certain point, for the loss of the main vasomotor center. If now the spinal cord is destroyed there is a second, and more serious, fall in blood pressure. After a time the blood pressure again rises, because a local automatic tonus develops in the arterial muscles.

Sections of the nerve stem above the medulla have little effect on the blood pressure and do not produce any fundamental disturbance in vasomotor reflexes. This well-known fact has been confirmed and amplified by Braun Menéndez. Stimulation of the hypothalamus provokes vascular reactions, and the cerebral cortex sends impulses that act on the arterial muscles in certain types of response, such as blushing, but these higher centers do not normally play a part in the maintenance of vascular tonus or in the fundamental vascular reflexes.

Cocainization, freezing, or destruction of the floor of the fourth ventricle on both sides of the mid-line produces the same effects as a transverse section of the spinal cord just below the medulla. Stimulation of the tovea on both sides of the mid-line provokes hypertension, and stimulation of the obex near the calamus scriptorius produces hypotension. It is doubtful whether there is a true vasodilator center.

The Mechanism of Vasomotor Activity

The permanent activity of the vasomotor center is due to the constant play of diverse influences. It is submitted to the action of agents brought to the center by the blood, to the products of its own metabolism, and to nerve impulses of multiple origin.

Humoral agents. CO_2 is the substance brought by the blood that has the most definite and well-demonstrated effect on the vasomotor center. Increased CO_2 in the blood causes general vasoconstriction; all the tissues become pale and the blood pressure rises. This response is more marked if both vagus nerves have been cut, because of the suppression of cardio-inhibitory reflexes that control hypertension; in this case the blood pressure may reach a level as high as twice the normal value (Fig. 102). Hypertension of asphyxia is due to accumulation of CO_2 in the blood. In extreme cases other metabolic products (*e.g.*, lactic acid) and anoxia may also stimulate the vasomotor center. The constrictor effect of CO_2 as described is due to its action on the center and not on peripheral structures; this can be clearly demonstrated by perfusing the head of an animal with hypercapnic (excess of CO_2) blood. The head of a dog *B* (Fig. 103) receives blood from another dog *A*. Cross circulation is maintained by anastomosing the carotid arteries and jugular veins of both animals.

A decrease in the CO_2 content of the blood causes a decrease in the activity of the vasomotor center, with general vasodilatation and hypotension. In extreme cases a state of shock may develop.

Changes in the chemical composition of the blood can also act indirectly on the vasomotor

Fig. 102. Effect of asphyxia on arterial blood pressure (registered with mercury manometer) of a curarized cat with both vagi cut. 1, artificial respiration is stopped; 2, artificial respiration is renewed; 3, the animal breathes in an atmosphere of nitrogen; 4, air is restored. (*Mathison, G. C., J. Physiol., vol. 41, p. 416, 1910.*)

center by stimulating chemoreceptors, such as the aortic and carotid bodies; in this case impulses are conducted to the center along afferent nerves.

Nervous influences. The activity of the vasomotor center is also under the influence of nervous impulses, which arrive from many parts of the organism and thus modify reflexly the diameter of the blood vessels. Somatic, visceral, and vascular reflexes will be considered.

Somatic reflexes. Stimulation of the central end of any somatic sensory nerve causes reflex changes in the diameter of the blood vessels. For example, electrical stimulation of the central end of the sciatic nerve provokes arterial hypotension or hypertension, according to the strength, frequency, and duration of the stimulus. Usually moderate stimulation causes hypertension (vasoconstriction) and strong stimulation causes hypotension (vasodilatation). Pain of moderate intensity causes vasoconstriction and paleness; intense pain causes vasodilatation, which is sometimes so marked as to bring about a state of shock.

Cold produces vasoconstriction in the skin, and heat produces vasodilatation. These re-
FIG. 103. Diagram of crossed-circulation experiment. The head of dog *B* is joined to the trunk only by the spinal cord; it receives its blood supply from dog *A*. Dog *C* is adrenalectomized; it receives blood from the adrenal of dog *B*. (*After Heymans, C., Arch. internat. de pharmacodyn. et de thérap., vol. 35, p. 269, 1929.*)

sponses form part of the mechanism that regulates the body temperature; they are accompanied by simultaneous vascular reactions in the splanchnic area, but in the opposite direction.

Visceral reflexes. Stimulation of the afferent fibers of visceral nerves (compression of the testes, pulling on the mesentery, etc.) provokes vascular reactions. The type of response is conditioned by the strength and other qualities of the stimulus.

Vascular reflexes. These are of great importance in the maintenance of arterial blood pressure. They are produced by impulses that arrive at the vasomotor center from receptors (pressoreceptors) situated in certain parts of the vascular system and travel along special paths, described when considering the nervous control of cardiac activity (see Chap. 17). The cardioaortic (de Cyon's depressor nerve) and Hering's nerves, which innervate the aorta and carotid sinus and are stimulated by a rise in arterial pressure, carry impulses not only to the cardioinhibitory center but also to the vasomotor center, which is inhibited, thus causing generalized vasodilatation, the intensity of which is proportional to the rise in pressure. Excitation of the cardioinhibitory center and inhibition of the vasomotor center combine in provoking a fall in blood pressure and thereby a return to the normal level. When the blood pressure falls below normal, the opposite reflex effects are produced, *i.e.*, tachycardia and vasoconstriction, and the blood pressure therefore rises.

Impulses from the vascular pressoreceptors are also carried to the respiratory center and provoke respiratory reflexes (see Chap. 32).

The nerve fibers innervating the aortic and carotid bodies carry impulses originated in chemoreceptors, sensitive to changes in the chemical composition of the blood. An increase in CO_2, a decrease in the pH of the blood, and anoxia (diminished oxygen tension) stimulate the chemoreceptors and provoke hypertension due to vasoconstriction (stimulation of the vasomotor center) and tachycardia (inhibition of the cardioinhibitory center) (Fig. 104). Several drugs injected into the blood also stimulate the chemoreceptors.

The aortic arch and the carotid sinus are the most important vasosensory areas for the regulation of the blood pressure. The pacinian corpuscles on the mesenteric arteries also discharge afferent impulses in relation to the degree of distention of the arterial walls, but the reflexes that these impulses provoke are not yet well known.

Drugs with inhibitory effects on the vasomotor nervous system.[1] Several drugs inhibit the transmission of vasomotor impulses along the sympathetic. They are useful auxiliaries in the treatment of certain diseases of the circulation, *e.g.*, arterial hypertension, and in the study of the pathogenesis of these diseases; they are also valuable in certain surgical procedures. These drugs may be classified into three main groups: (*a*) agents with central activity which block vasomotor reflexes (cardioaortic, carotid sinus) at the vasomotor centers, *e.g.*, *plasmochin*,[2] *pentachin*,[3] and the central blocking component of ergot;[4] (*b*) antiadrenergic agents which block sympathetic impulses at the periphery and inhibit the effects of adrenaline and noradrenaline, *e.g.*, *dibenamine*,[5] and priscol (benzylimidazoline);[6] (*c*) agents which block sympathetic and parasympathetic ganglia and which not only do not inhibit pressor effects of adrenaline and noradrenaline in animals and man but reinforce them; the best known is tetramethylammonium chloride.[7] Derivatives of polymethylene-bis-trimethylammonium[8] also have interesting pharmacological properties. The C^{10} compound, known as decamethonium, has curarizing activity; the C^5 and C^6 compounds, called *pentamethonium* and *hexamethonium* respectively, exert a blocking action on the ganglia, which in man lasts longer and has fewer side effects than other drugs used for this purpose. Good results have been reported in the treatment of certain cases of arterial hypertension.[9]

Humoral Agents That Act Directly on the Arteries

Vasomotor nerves release chemical mediators that act on the arterial muscles. Nerve action is ultimately the result of a chemical action; it is not surprising, therefore, that chemical substances in the blood may produce contraction and relaxation of the arterial muscles. These substances are (*a*) products of tissue metabolism; (*b*) hormones produced by the endocrine glands.

Products of tissue metabolism that act directly on the arterial muscles usually provoke vasodilatation. CO_2, lactic acid, other acids, adenylpyrophosphate, etc., are some of the principal substances that act in this way. Probably they are of importance in the production of the local vasodilatation that occurs when a tissue increases its activity. Increased activity causes greater production of these metabolic substances. There is considerable vasodilatation in active muscles, which is probably caused by this mechanism.

Hormones play a considerable and complex part in the regulation of arterial diameter and therefore of the blood pressure. Some hormones, *e.g.*, adrenaline, secreted by the adrenal medulla, and vasopressin, produced by the neurohypophysis, have a direct and marked effect. Adrenaline has a vasoconstrictor effect on all the arteries with the exception of those of the heart. It is active in cases of emergency when there is a disturbance in the functional equilibrium, but it is not indispensable for the maintenance of arterial tone and normal blood pressure.

Vasopressin also has a general vasoconstrictor

Fig. 104. Principal mechanisms that control the tonus of the blood vessels. *VMC*, vasomotor center; *AxR*, axon reflex; *PSD*, parasympathetic vasodilators; *DRD*, dorsal root dilators; *SC*, sympathetic vasoconstrictors. (*After Heymans, C. and J. J. Bouckaert, Ergebn. d. Physiol., vol. 41, p. 28, 1939.*)

activity, but it is less marked in the cerebral, renal, and pulmonary areas. It is not yet possible to say how important vasopressin is for the maintenance of arterial blood pressure, except in amphibians, in which the part it plays in maintaining vascular tone and blood pressure has been demonstrated.[1]

Kalikrein and vagotonin are vasodilating substances obtained from pancreatic extracts, but their hormonal nature has not been demonstrated.

The influence of the endocrine glands on the diameter of the blood vessels and blood pressure will be considered in the chapters on each gland.

The principal factors that take part in the maintenance and regulation of blood pressure are represented diagrammatically in Fig. 104.

Hypertensin (angiotonin). Renal ischemia produced by partial occlusion of the renal artery[2] is due to the release into the blood stream of a specific substance.[3] The work of Braun Menéndez *et al.*[4] and of Page *et al.*[4] has shown that the ischemic kidney discharges renin, a protein that acts as an enzyme and transforms an α globulin in the blood (known as "hypertensinogen") into a powerful vasoconstrictor, hypertensin (called "angiotonin" by Page) (Fig. 94). This mechanism probably plays a part in some cases of human hypertension. Renin is discharged by the kidney and hypertensin is formed when there is a marked fall in blood pressure (hemorrhage, anaphylactic shock); therefore this mechanism probably plays a physiologic part in the recovery of normal blood pressure in these conditions (see "Arterial hypertension of renal origin," Chap. 63).

Role of arterial contractility. The muscles of the artery are an important factor in the maintenance and regulation of blood pressure; they also regulate the circulation through the different vascular territories and organs. In this last respect they are a factor in the circulatory balance between the somatic and splanchnic areas in muscular exercise, in the regulation of body temperature, in renal and other secretions, and in the water balance between the blood and tissues.

Effect of sympathectomy on vasomotor tone. Surgical removal of segments of the sympathetic

ganglion chain produces vasodilatation in the territory innervated by the fibers which are thus disconnected from the centers. Sympathectomy has been performed in human subjects in order to relieve arterial hypertension. A certain degree of vasomotor tone is, however, recovered after a time, and it has been postulated that ganglionectomy does not sever all vasoconstrictor fibers.[1] Moreover, in some patients autochthonous vascular resistance that is not of nervous origin may occur after sympathectomy, but so far there is no satisfactory explanation for this development.[2]

Arterial hyperten ion. A blood pressure above the normal is frequently observed in adults of both sexes. In some cases it is possible to attribute this hypertension to a definite pathologic condition of which it is a sign, *e.g.*, in many acute and chronic renal diseases. In other cases, even careful and detailed examination reveals no other disturbance except hypertension. This so-called "essential hypertension" is one of the major problems of medicine that still awaits a solution. Its cause is unknown, and the mechanisms that take part in it are insufficiently understood; treatment of the disease is therefore symptomatic and empirical. A recent important advance has been the discovery of the mechanism of hypertension due to renal ischemia (renin-hypertensin). Experimental, more or less permanent, hypertension has been obtained by cutting the cardioaortic and Hering's nerves on both sides. Hypertension has also been obtained experimentally by injecting kaolin into the cisterna magna, thus provoking an increase in cranial pressure. The latter two types of hypertension differ in several ways from human cases of hypertension.

Wiggers[3] has made a careful examination of the mechanism of production of hypertension, examining diastolic, systolic, and pulse pressures and the shape of the pulse waves. Three factors can enter into play: (*a*) increase in heart rate and systolic discharge; (*b*) decrease in caliber and elasticity of the great arteries; (*c*) increase in resistance at the level of the arterioles. The first factor can be eliminated, because many observations have shown that the minute volume and systolic discharge are within normal ranges in patients with hypertension. Peripheral resistance, on the other hand, is increased, and there are signs of diminished

distensibility of the aorta. There is no direct relation between the severity of arterial lesions (arteriosclerosis) and arterial hypertension; moreover, arteriosclerosis and hypertension can be observed separately. Probably functional disturbances provoke structural lesions at a later date. Nothing so far known opposes the theory that human hypertension can be produced by a humoral agent such as hypertensin, but the presence of this substance in human blood has not been demonstrated (see Chap. 63).

Local vascular spasms. *Intermittent claudication due to arterial spasm.* Intermittent functional claudication is a characteristic condition resulting from a local and persistent vasoconstriction (angiospasm). In typical cases, owing to the constriction of the main artery of one or both legs, the circulation is sufficient only at rest or in moderate exercise of short duration, but becomes insufficient in heavy or prolonged exercise. The patient suffers intense pain and difficulty in moving the limb when he makes a heavy or prolonged effort. The pain disappears with rest and walking can be continued, but claudication reappears as soon as the effort is renewed and sustained for a certain time. Incomplete arterial occlusion due to degenerative processes of the arterial walls (thrombosis, embolism) produces the same syndrome. Differential diagnosis between functional claudication due to arterial spasm and that due to an organic arterial lesion is very difficult in some cases.

Many acute and paroxysmal visceral pains have been attributed to arterial spasm.

Raynaud's disease. In this disease there is symmetrical arterial spasm in the fingers of both hands. The fingers become first cold and livid and then cyanotic; there is intense pain as long as the spasm lasts. The angiospastic crises are sometimes so intense and prolonged that trophic lesions are produced, and gangrene of the fingers may occur.

CHAPTER 21

The Arterial Pulse

THE ARTERIAL PULSE consists in a sensation of expansion felt, simultaneously with the heartbeat, when an artery is slightly pressed between finger and thumb or when it is lightly pressed through the skin and soft tissues against a resistant surface. This sensation is due to the spread along the arteries of a pressure wave originated by the systolic discharge into the aorta. Slight pressure must be exerted on the artery to counteract the permanent distention of the arterial wall, thus facilitating the perception of changes in internal pressure. If the pressure exerted is too great the artery will be completely occluded and the pulse will be suppressed. Systolic pressure waves traveling down the arteries cause a small expansion of their walls, but this movement is not easily seen or felt if a slight external pressure is not applied.

The systolic pressure wave also provokes elongation of the arteries, and this can be clearly seen if an artery is ligated; at each pulse wave the ligature is pushed forward in the direction in which the wave spreads. This movement can be registered by cutting the artery just below the ligature and connecting it with a recording lever.

In arteries that describe a curve the pressure wave tends to open the arch, sometimes with considerable force. The slight rhythmical extension of the leg coinciding with the heartbeat, observed in subjects with one leg crossed over the other, is due to this expansive force. Rhythmical movements of the head synchronous with the heartbeat have the same origin.

All these movements of the artery caused by the spread of the systolic pressure wave are known as arterial locomotion.

The arterial pulse is one of the aspects of body function most frequently examined by the doctor. The development of more direct and informative methods of exploration of cardiac activity has somewhat diminished its importance; the study of the pulse, nevertheless, continues to be an almost indispensable source of information in routine medical examinations. It is therefore necessary to understand its significance thoroughly in order to appreciate the possibilities and limitations inherent in its study.

Registration of the arterial pulse. A graphic record of the arterial pulse gives a good knowledge of its properties, and palpation of the pulse is rendered more valuable in the light of the information acquired by the study of pulse records. The arterial pulse can be recorded by dissecting the artery and inserting in it a cannula connected to a recording manometer, or else by amplifying and recording the oscillations of the arterial walls caused by pressure changes. The former is a record of arterial blood pressure variations and is commonly used in experimental animals, but only in special circumstances in man. Optical manometers of great efficiency should be used (Wiggers, Hamilton). The second method is the one usually applied in the study of the human pulse.

The record obtained when a calibrated manometer is connected with the artery allows the quantitative estimation of the different pressures occurring throughout the cardiac cycle, but when oscillations of the arterial walls are recorded, only a qualitative appreciation of pressure changes can be made. In this latter case, if pressure values are desired, they must be obtained separately by one of the sphygmomanometric methods described in Chap. 19, and only the pressures at the peak (systolic) and the beginning (diastolic) of the pulse wave are measured.

Pulse-wave records obtained by connecting the different arteries with a manometer could

have been described when considering the variations in arterial blood pressure, but this description will be given in this chapter because pressure changes are the fundamental cause of the pulse.

very short time most of the energy developed by ventricular contraction is employed in overcoming the inertia of the column of blood and in distending the arterial walls, and consequently a very small amount is transformed into
FIG. 105. Aortic and left intraventricular pressure curves. Upper curve (aortic pressure): *A-B*, preliminary wave; *B-C*, minimum ejection subphase; *C-D*, maximum ejection subphase; *D-E*, reduced ejection subphase; *E-F*, aortic incisura. Letters on the lower (ventricular pressure) curve, the same as in Fig. 35. Time in 0.04 sec.

The aortic pressure curve. Figure 105 reproduces a record of aortic (upper tracing) and left intraventricular (lower tracing) pressures, simultaneously taken with Wiggers' optical manometers inserted respectively in the root of the aorta just beyond the semilunar valves and in the left ventricle. Systolic events begin in the aorta with a small wave *A-B*, which coincides with the end of ventricular isometric contraction. This wave and another, which in some cases precedes it and coincides with auricular systole, are Frank's preliminary waves.

Important changes in aortic pressure begin with the opening of the semilunar valves (*N*) and the commencement of the ejection phase. When ample communication between the ventricle and aorta is first established, during a kinetic energy moving the blood forward. This is the subphase of minimum ejection (*B-C*). Then there is a change in the pressure gradient because the systolic impulse is balanced by the runoff toward the periphery. This is the subphase of maximum ejection (*C-D*). When the loss of pressure through displacement of blood toward the capillaries predominates over the pressure developed by the ventricle, the record marks a descending curve of slow gradient (*D-E*). This is the reduced ejection subphase.

At *E* the pressure begins to fall rapidly, and in the records the curve appears as if it had been suddenly cut; this has been called the aortic incisura by Frank. The explanation of this phenomenon usually given is that at *Q* (in the ventricular record) the majority or all of the

ventricular fibers have completed their contraction and the whole ventricle, en masse, begins to relax. The drop in pressure, which continues in the ventricle, is suddenly interrupted in the aorta by closure of the semilunar valves (*F*). This produces a series of sharp oscillations in the arterial pressure, which are marked by vibrations known as postincisural vibrations. The pressure and tension of the arterial walls then fall gradually because of the runoff into the capillaries. The record descends at a slow gradient until at the next systole the cycle begins again.

These pressure changes in the aorta, transmitted in a wavelike manner along the arteries, are the fundamental cause of the pulse. As they travel to the periphery they are increasingly modified. The arterial tubes, because of the elasticity and distensibility of their walls, are better adapted for an efficient utilization of cardiac energy than for the faithful transmission of small pressure oscillations. The fundamental pressure pulse is also modified by the movement of the blood and by reflected waves arising in the periphery of the arterial system.

The carotid pressure curve. Figure 106 reproduces a typical record of pressure changes in the carotid artery of the dog, obtained by inserting a Wiggers manometer in the right carotid, near its origin in the aorta. Curves obtained at this level usually exhibit a small, brief oscillation (*A-B*) corresponding to the preliminary wave seen in the aortic pressure pulse during isometric contraction of the ventricle.
Fig. 106. Carotid pressure curve in the dog, registered with Wiggers' universal manometer (upper curve); simultaneous ECG (lower curve). *A-B*, preliminary wave; *B-C-D*, primary peak; *B-E*, minimum and maximum ejection subphases; *E-F*, reduced ejection subphase; *F-G*, incisura; *H*, postincisural vibrations. Time in 0.2 sec.

After the opening of the aortic semilunar valves the pressure rises in an almost vertical straight line, which is suddenly interrupted by a short fall (*B-C-D*), thus forming a sharp peak. This oscillation, which is not seen in the aortic pulse, is due to the inadequacy of the arteries for the faithful transmission of pressure changes. The curve is the same as that which would be obtained if a cannula were placed in the aorta and connected with the manometer by an elastic tube with the same properties as the artery. The efficiency of the manometer is decreased because the distensible tube diminishes the volume-elasticity coefficient and increases the effective mass of the system. The rapid rise in pressure and the change in gradient of the aortic pulse are therefore not faithfully recorded; they are replaced by the sharp peak just mentioned, caused by the vibration of the liquid mass in the arteriomanometric system. This peak will become more marked the quicker the rise in pressure and the greater the distensibility of the artery. It portrays the natural frequency of vibration of the arteriomanometric system. Usually there is only one

peak, but several vibrations can be observed if the blood pressure is low or when the blood is ejected from the ventricle with unusual force.

A period of rising pressure (*D-E*) follows, showing sometimes small irregularities of the same nature as the primary peak, though less prominent. After reaching a maximum, the pressure falls slowly (*E-F*) until, with the beginning of ventricular relaxation, it falls sharply (*F-G*) as in the aortic incisura. The fall in pressure is suddenly stopped by the closure of the aortic semilunar valves. A kind of rebound causes one or more postincisural vibrations (*H*) in the pressure curve, which continues to descend until the following systole again causes it to rise.

Fig. 107. Marey's direct-transmission sphygmograph.

Registration of the human pulse. Sphygmography and sphygmograms. Sphygmography is the technique used in registration of the pulse by means of instruments called "sphygmographs," which give records known as "sphygmograms." The majority of the instruments have been designed for registration of the radial pulse.

Sphygmographs have been developed from the instrument first invented by Marey.[1] This consisted in a button applied with a certain pressure over the radial artery by a leather bracelet; it transmitted the expansion of the artery to a lever recording the movements on a smoked surface (Fig. 107). Another model transmitted the movements to a tambour, and the changes in pressure in this tambour were recorded by a second one to which it was joined by a rubber tube (Fig. 108). Direct-transmission sphygmographs, such as Jacquet's, are no longer used. Indirect-transmission sphygmographs have been developed by Frank, Wiggers, and others, using the Frank segment capsule for optical registration.

The carotid and subclavian pulses are registered by adapting to the skin, over the artery, a small glass, wood, or metal funnel, 2 cm. in diameter, connected by a rubber tube with a segment capsule for optical registration. A small lateral opening in the tube allows equilibration of the internal and atmospheric pressures.
Fig. 108. Marey's indirect (pneumatic) transmission sphygmograph.

The pulse in the arteries of the arms or legs can be registered at different levels by means of a pneumatic cuff, such as those used to measure the blood pressure, joining it to a Marey tambour or a Frank segment capsule through a Chauveau and Marey sphygmoscope (Fig. 109). A sphygmoscope consists of a large

[1] Marey, E. J., "La Méthode graphique," 2d ed., Masson et Cie, Paris, 1885.

glass tube closed by two perforated rubber stoppers. One of the stoppers is covered by a rubber finger stall which is connected by a tube (*a*) to the pneumatic cuff; the other stopper has a small glass tube connected to the Marey tambour or Frank capsule; a lateral opening serves to balance the internal and atmospheric pressures. This apparatus is well suited for recording the pulse in small children, in whom it is difficult to obtain a record of the subclavian or radial pulse.

Fig. 109. Apparatus for optical registration of the arterial pulse of a limb. *M*, manometer; *I*, insufflator; *S*, sphygmoscope; *F*, Frank's segment capsule; *A*, arm cuff; *L*, source of light. (*A. S. Segura, 1937.*) On the right: sphygmoscope. Description in text.

Central, intermediate, and peripheral arterial pulses. The fundamental pressure pulse produced in the aorta by the systolic discharge undergoes considerable changes as it travels down the arteries. Sphygmograms will therefore vary according to the distance from the origin of the aorta at which they are taken. A central, an intermediate, and a peripheral arterial pulse are usually considered. In man the central pulse can be recorded near the origin of the common carotid or subclavian arteries; the intermediate pulse, in the upper segments of the carotid, femoral, and brachial arteries; the peripheral pulse, in the arteries of the distal part of the limbs (radial and pedal arteries).

Terminology. Anacrotic and catacrotic events. The pulse wave in a sphygmogram consists of an ascending limb, a peak or summit, and a descending limb. Oscillations in the ascending limb are called "anacrotic" (Greek *ἀνά*, up, and *κρότος*, stroke), and those in the descending limb "catacrotic" (*κατά*, down). The primary peak in the central pulse is an anacrotic event; the dicrotic wave of the peripheral pulse and the incisura of the central pulse are catacrotic events. The central pulse shows anacrotic and catacrotic oscillations; the peripheral pulse usually has only catacrotic oscillations.

The central pulse in man. The central pulse in man is recorded by placing a funnel in the supraclavicular fossa with sufficient pressure to suppress the pulsation of the jugular vein; a segment capsule connected with the funnel by a rubber tube gives an optical record of the arterial pulse. The features of this pulse are essentially the same as those seen when an optical manometer is inserted into the aorta of a dog. Figure 110 should be compared with Fig. 106. The former is a record of the human subclavian pulse (upper tracing) and the carotid pressure pulse of the dog obtained with a Wiggers optical manometer. Frequently there is no primary peak in the central pulse; in these cases its curve is the same as that of the aortic pressure pulse (Fig. 111).

The following events of the cardiac cycle can be established with great accuracy in a central sphygmogram: (*a*) the duration of the ejection phase (Fig. 110, *B-F*), with the subphases of maximum ejection (*B-E*) and reduced ejection (*E-F*); (*b*) the duration of the protodiastolic

phase (*F-G*); (*c*) the total duration of ventricular diastole. With less accuracy, the preliminary wave (*A-B*) gives the duration of isometric contraction. If, as occurs in some cases, an auricular wave is marked in the sphygmogram, it is also possible to measure the A-V conduction time. The gradient of the upward stroke gives an idea of the velocity of ventricular ejection: the higher the velocity, the steeper the gradient. Finally, in cases of aortic stenosis, vibrations due to the systolic murmur appear in the ascending limb and throughout the greater part of the ejection phase.

The intermediate pulse in man. The sphygmogram of the intermediate pulse obtained by optical registration of the distal part of the carotid, or the brachial artery, diagrammatically represented in Fig. 112 (curve III), differs from the central pulse by the following features: (*a*) preliminary waves are not seen, or are only slightly marked; (*b*) a notch replaces the primary peak; (*c*) the incisura is less sharp; (*d*) postincisural vibrations are damped and tend to fuse into a single wave of longer period. Simultaneous records of the central and intermediate pulses show a greater delay in the beginning of the latter with respect to cardiac events.
Fig. 110. Central arterial pulse in man (upper curve) and carotid pressure pulse in dog (lower curve). *A-B*, preliminary wave during the isometric contraction; *B-C-D*, primary peak; *B-E*, maximum ejection; *E-F*, reduced ejection; *F-G*, incisura (protodiastole); *H*, oscillations caused by closure of the semilunar valves. Time in 0.2 sec. in the upper record and in 0.04 sec. in the lower.

The peripheral pulse in man. The peripheral sphygmogram, such as is obtained from the radial artery, differs widely from a central pulse record. All minor vibrations are fused in the former into two waves per heart cycle; their contour is smooth and their period long. Curve IV, Fig. 112, is a diagrammatic representation of a radial sphygmogram, optically recorded; Fig. 113 reproduces an optical tracing of the radial pulse simultaneously recorded with the venous pulse. The following features can be easily recognized: preliminary waves have disappeared completely in the peripheral sphygmogram; the wave corresponding to the ejection

phase in the central sphygmogram constitutes the primary or principal wave in the peripheral pulse; it has a smooth contour; the incisura is not marked; closure of the semilunar valves, portrayed as an acute angle in the central pulse, cannot be recognized in the peripheral one. A rounded curve, concave upward, joins without any definite break the primary and secondary (also called dicrotic) waves. The dicrotic wave (Greek δις, two, and κρότος, stroke), so called because when it is pronounced it gives a sensation of a double pulse, is due to the vibrations caused by closure of the semilunar valves, their contour being modified as they are transmitted down the arteries. Sometimes the dicrotic wave is reinforced or its shape modified by interference or resonance phenomena produced by waves reflected from the periphery. It is no longer believed that the dicrotic wave is due mainly to these reflected waves.

FIG. 111. Central pulse in normal human subject. Carotid pulse, heart sounds, ECG, and time in 0.2 sec. The central pulse record is similar to the aortic pressure record.

Circulatory conditions in fever are favorable for the accentuation of the dicrotic wave. Dicrotism is especially developed in typhoid fever, in which there is a clear sensation of a double pulse. (For details on the cause and significance of dicrotism, see Wiggers.[1])

There is a considerable delay of the peripheral pulse with respect to the central pulse (0.05 to 0.08 sec.).

The information given by the radial pulse regarding cardiac function is rather meager. The heart rate and the regularity and relative amplitude of the beats constitute the main data that can be gathered from its study. The central sphygmogram optically recorded is richer in details and can give additional exact points of reference for determining the duration of several phases of the cardiac cycle. In man the only nonsurgical method that permits a detailed analysis of all the phases of the cardiac

cycle is the simultaneous registration, by optical methods, of the central arterial and the venous pulses (Fig. 114).

The characteristics of the pulse. The pulse will be considered from a medical point of view, in respect to both the sequence of beats and the characteristics of the waves. Palpation of the radial pulse will be compared with the results of graphic registration, which gives more precise details and a permanent record.

The general characteristics of the pulse are: (*a*) amplitude; (*b*) equality; (*c*) regularity; (*d*) tension; (*e*) frequency.

Amplitude is due to expansion of the artery and is marked on the records by the height of the pulse wave. There is an ample pulse (pulsus magnus) if, on palpation, there is a clear sensation of the fingers being lifted, and a high pulse wave is recorded in the sphygmogram. Apart from factors due to exploratory methods (the degree of pressure exerted on the artery, etc.), amplitude varies as the pulse pressure in the

artery. If the amplitude is small the pulse is known as a small pulse (pulsus parvus).

Equality in the pulse refers to the relative amplitude of the different beats. When the pulse is normal all the pulsations have the same amplitude. An alternating pulse consists in the regular alternation of a large and a small pulsation; this is a typical instance of an unequal pulse. The so-called "paradoxical" pulse (pulsus paradoxus) is another example: the pulse wanes during inspiration, because the blood pressure falls owing to the fall in intrathoracic pressure (see "Respiratory fluctuations" in Chap. 19, Circulation in the Arteries).

Regularity in the pulse refers to the relative duration of the intervals between the pulse waves. The pulse is regular or irregular according to whether the beats are separated by intervals of equal or unequal duration. Premature beats, auricular fibrillation, incomplete heart block, and respiration are the main causes of irregularity in the pulse. The term "rhythm" originally referred to the regularity of the pulse, but it has acquired a wider significance, including three properties of the pulse: equality, regularity, and frequency. If a pulse is equal, regular, and of normal frequency it is a normal rhythmic pulse. If, on the contrary, any or all of these three properties are abnormal there is arrhythmia. Complete arrhythmia, such as occurs in auricular fibrillation, involves abnormality in all three properties.

Tension or hardness of the pulse is measured by the force necessary to suppress the pulse wave and is therefore a qualitative estimation of systolic pressure. It is of little value, because it is entirely subjective, but it can give a general idea of the blood pressure. Sphygmomanometric determinations should always be made. Hypertension causes the pulse to harden (pulsus durus) and hypotension softens it (pulsus mollis). Arteriosclerosis hardens the arteries and can give a false impression of the tension or hardness of the pulse; it should always be borne in mind, especially in elderly subjects.

Frequency of the pulse is given by the number of pulsations per minute; therefore it depends fundamentally on the heart rate. The normal frequency in adults, after a few minutes' rest, is 75 to 85 beats per minute when lying down. Increased frequency is called tachycardia (pulsus frequens); if the rate is 60 or less per minute there is bradycardia (pulsus rarus). Sometimes the pulse rate is lower than the heart rate, because some of the systoles do not eject blood into the arteries; in this case there is bradysphygmia. The heart rate, therefore, cannot be determined with certainty by counting the pulse.

The characteristics of the individual pulse wave are of special interest in some cases, as those of dicrotism already mentioned (fevers, typhoid fever, etc.). In cases of arterial hypertension, and especially in cases of aortic insufficiency, the artery expands and retracts very rapidly; sphygmograms show steep gradients in the ascending and descending limbs of the pulse wave (pulsus celer or Corrigan pulse). In aortic stenosis, on the contrary, the artery expands slowly and there is a low gradient in both limbs of the pulse curve (pulsus tardus).

Velocity of transmission of the pulse wave. The pulse does not begin simultaneously in all the arteries; there is an appreciable interval between the central and peripheral pulses. The speed of transmission can be measured by simultaneously recording the pulse in two distant points of the same artery, or in an artery and one of its branches. If the interval between the waves in the two records and the distance between the points at which they have been registered are accurately measured, the velocity of transmission of the pulse wave can be determined. The figure usually found is 7 to 9 m. per sec.

The average velocity of blood flow in the arteries is 50 cm. per sec., but the pulse is transmitted at much greater speed; therefore the pulse is not caused by the arrival of the blood ejected by ventricular systole to the point where the pulse is registered. A comparison may be helpful: if an object is floating downstream on a river, the movement of this object with respect to the river banks shows the velocity of flow. If now a stone is thrown into the river, upstream with respect to the floating object, the ripples caused by the stone will overtake and pass the floating object, because the speed of these pressure waves is greater than the velocity of flow.

Several factors condition the velocity of transmission of pulse waves. Moëns[1] correlated these factors and expressed the results mathematically. Lambrosi, in a recent study of this question,[2]

[1] Moëns, A. I., "Die Pulskurve," Brill, Leiden, Netherlands, 1878.

[2] Lambrosi, P., *Helvet. physiol. et pharmacol. acta.* **8**, 209, 1950.

concludes that a more accurate expression is given by what he calls the Moëns-Kortweg equation:

$$V = \frac{1}{\sqrt{\frac{d}{E} + \frac{2dR}{a_1E_1}}}$$

in which V is the velocity of the pulse wave, d is the specific weight of the fluid, E is the module of elasticity of the whole tube, a_1 is the thickness of the wall of the tube, and R is the radius of the cross section of the lumen of the tube.

The delay in the transmission of the pulse wave. An interval elapses between the beginning of ventricular systole (as registered by the apex beat or the first heart sound) and the beginning of the pulse wave in the explored artery. This delay is too small to be measured otherwise than by accurate graphic registration. The greater the distance from the heart, the longer will be the delay.

Part of this delay is common to all the arteries, including the aorta. Before the blood can be ejected into the arteries the ventricle must raise the pressure above the diastolic arterial pressure, *i.e.*, there is the isometric contraction phase. The rest of the delay is due to the time the pulse takes to spread down to the point explored; it varies for each artery and increases with the distance from the heart. The pulse at the origin of the aorta shows only the first or essential delay. Other arteries add their own to this delay; it is 0.01 to 0.02 sec. in the common carotid and subclavian arteries, and 0.06 to 0.08 sec. in the radial artery (Fig. 112).

CHAPTER 22

Functions of the Capillaries

THE CAPILLARIES ARE the blood vessels with the thinnest walls and the smallest diameter. "Capillary vessel" literally means a vessel as thin as a hair, but the capillaries are much finer than hairs. They divide and anastomose to form a net, which contains in its meshes the cells of the tissues and organs. Blood reaches the capillaries from the arteries, which divide and subdivide, the walls becoming thinner, until without any sharp transition the small arterioles are converted into capillaries. The capillaries converge and form vessels of increasing diameter which, also without transition, are gradually surrounded by muscle fibers until a complete coat, with little elastic tissue, is formed; these vessels are the small veins.

The primary genetic unit of vascular tissue is the capillary. The first vessels to appear in the embryo (Wolff's islets, opaque area) are capillaries formed from mesenchymatous cells. In the early stages of development there are no other vessels. Primitive erythrocytes are also formed by the proliferation of the cells in the capillary walls. After birth, hemopoietic activity is limited to the sinusoid capillaries of bone marrow (see Chap. 5). All the vessels, even the largest, *i.e.*, the aorta, have developed from capillaries; and the heart, although a complicated organ, is at first a capillary tube. Capillaries have therefore a potential capacity to develop into blood vessels of any kind.

The proliferative activity of the capillaries is considerable in the embryo and throughout the period of growth. This activity is responsible for the formation of new vascular territories in the growing tissue. It is never completely lost, and in adult life new capillaries and blood vessels can be formed in response to adequate stimuli. Capillary proliferation is evident in the process of healing wounds, in the organization of clots, and when tissues develop in certain functional conditions, *e.g.*, the uterus and mammary glands during pregnancy. The capacity to form more complicated blood vessels also persists in the adult. When there is gradual arterial occlusion, a new arterial system is developed from the existing arterioles and capillaries. Collateral circulation developed in response to venous occlusion is formed in the same way.

The main object of the circulatory function is the continuous conveyance of blood to and from the capillaries. In these vessels exchanges take place between the blood and the tissue fluids which are the immediate environment of the cells. The chemical composition and physical properties of these fluids, *i.e.*, the conditions necessary for the life of the cells, are dependent on these exchanges. The capillaries are therefore of fundamental functional importance.

Morphology. There is good evidence for the existence of three structural components of the capillary wall: (*a*) the endothelium, made up of pavement-like cells joined by an intercellular cement; (*b*) an endocapillary lining, which is noncellular and is possibly derived by absorption from the circulating blood proteins; (*c*) a pericapillary sheath, with characteristics common to the surrounding connective-tissue matrix, which serves as an external supporting layer.[1]

The endothelium is, undoubtedly, the most important part of the capillary wall. Substances passing into or out of the capillaries probably do so through the intercellular cement, but this cement is produced by the endothelial cells and its physiologic properties are maintained by them. The physical properties of the cement are conditioned by the pH and the calcium content of the surrounding fluid. Normally intercellular

[1] CHAMBERS, R., and B. W. ZWEIFACH, *Physiol. Rev.*, 27, 436, 1947.

cement is being continually renewed. Leukocytes can penetrate through the intercellular cement and migrate out of the capillaries (diapedesis). The breach thus made is rapidly filled, and the integrity of the capillary wall is completely restored.

FIG. 115. Apparatus for direct observation of the capillaries of the skin bordering the nail.
FIG. 116. Capillaries of the skin bordering the nail. The loops are a deep red. Careful observation reveals the movements of the red cells (not evident in picture) and the occasional closure and opening of capillaries.

The average length of a capillary is 0.5 mm. (0.2 to 0.8 mm.), and the diameter varies from 5 to 20 μ. The erythrocytes must therefore change in shape to pass through the narrowest capillaries. An individual capillary is a minute structure, but the whole capillary system is of enormous size. The capillaries of a man weighing 50 kg., if joined end to end, would extend to a length of 100,000 km. (several times around the earth), and their total surface would cover 6,300 sq. m. (about 1½ acres).

Capillaroscopy. Microscopic observation of the capillaries *in vivo* is a common laboratory demonstration, very easy to perform in more or less transparent membranes or tissues such as the mesentery or the lung of the frog.

Human capillaries can be readily observed under the microscope in the skin around the root of the nail, if transparency of the outer layers is increased by treating it with glycerine or mineral oil. A powerful light is reflected on the surface of the skin (Fig. 115). Still and moving pictures of the capillaries can be obtained with a similar arrangement (Fig. 116).

Terminal circulatory units. The shape and distribution of capillaries vary in different organs and tissues. Mostly, however, they form part of structural and functional units. In tissues in which the circulation does not have to respond to complex functional adaptations, the capillaries are not organized. In others, in which there are more versatile functional conditions, *e.g.*, the intestinal tract and the muscles, the distribution

and regulatory mechanisms are more complicated. When the tissue is resting, blood flows only along certain channels; when activity increases, it flows through the whole capillary network.

thousandth of the velocity in the aorta. At this speed an erythrocyte takes about one second to move along the whole length of the capillary.

The blood pressure in the capillaries cannot be easily determined. The most accurate method
Fig. 117. Schematic representation of the structural pattern of the capillary bed. The distribution of smooth muscle is indicated in the vessel wall A. V. A., arteriovenous anastomosis. (*Zweifach, B. W., in "Factors Regulating Blood Pressure," Trans. Third Confer., Josiah Macy, Jr., Foundation, New York, 1949.*)

The capillaries, anastomosing with each other and connecting with the artery in which they arise and the veins where they end, form a terminal circulatory system[1] (Fig. 117). The arteriovenous channels of preferential circulation act as thoroughfares for blood flow. The metarteriole and the precapillaries at the proximal end of the terminal unit have muscle fibers which intermittently open the precapillary sphincteric offshoots. This mechanism regulates the circulation through the tissues. The true capillaries which follow have no muscle fibers and by multiple anastomoses form a complex network. This network is drained by postcapillaries into the distal portions of the preferential channels. Arteriovenous anastomoses arising above the metarteriole and ending in the venule provide a short circuit which gives even more functional plasticity to the system.

Velocity of flow and blood pressure in the capillaries. The velocity of flow in the capillaries can be determined directly by microscopic observation. The time taken by a red cell to travel a known distance is measured, and the speed is then calculated. The usual velocities are of 0.5 to 0.8 mm. per sec., about one-

[1] Chambers, R., and B. W. Zweifach, in "Factors Regulating Blood Pressure," Transactions of Third Conference, Josiah Macy, Jr., Foundation, New York, 1949.

is to introduce by micromanipulation a microcannula into the capillary, connecting it with a suitable manometer. This technique, developed by Rehberg and Carrier, has been applied in man by Landis.[1] A transparent microcannula filled with saline was introduced into a capillary in the skin. The cannula was connected to a manometer and an insufflator. When the pressure in the system was below the pressure in the capillary, blood flowed out to the cannula, and when the pressure was raised above that in the capillary, saline was injected. By equilibrating the pressures it was possible to measure the exact capillary pressure. The following average values were found in the capillaries of the skin over the nail bed in normal subjects lying down, and with the hand at the level of the manubrium of the sternum (point of reference for the level of the heart): arterial side, 32 mm. Hg; curve of loop, 20 mm. Hg; venous side, 12 mm. Hg. The pressure therefore falls considerably in the short distance between the artery and vein. There is a pulse pressure of 5 to 10 mm. in the arterial end, *i.e.*, capillary pressure when measured in systole is 5 to 10 mm. higher than when measured in diastole. At the venous end there is no appreciable difference between the pressure measured during diastole and systole.

If the finger is lifted above the level of the

[1] Landis, E. M., *Heart*, **15**, 209, 1930.

manubrium, the pressure rises slightly in the arterial side and is not changed in the venous side. If the finger is placed below the level of the heart, the pressure rises in the arterial and venous sides because of the hydrostatic effect. If venous circulation is obstructed, capillary pressure rises up to 10 mm. Hg above the venous pressure. Arterial vasodilatation causes a marked rise in pressure through the entire length of the capillary (from 40 to 60 mm. Hg in the arterial end, and from 10 to 40 mm. Hg in the venous end); pulsation also becomes evident. The increase in pressure caused by venous obstruction is due to the damming effect of the obstacle; that caused by arterial dilatation is due to lowering of peripheral resistance so that a larger proportion of the arterial pressure is transmitted to the capillaries.

Little is known about the pressure in the capillaries of the deeply situated vascular territories. In the glomerular capillaries of the kidney, owing to the proximity of the aorta and to the rapid branching of the renal artery, the blood pressure is much higher than in the skin capillaries; in mammals it has been calculated as being from 70 to 90 mm. Hg. This high capillary pressure is important in the process of glomerular filtration (see Chap. 63).

Capillary pressure is one of the main factors in the exchange of substances between the blood and tissue fluids through the capillary endothelium.

CHANGES IN CAPILLARY DIAMETER

The capillaries in the body are not all open and functioning at the same time. If they were, all the blood would be poured into the capillaries and would stagnate there; the circulation would stop. The number of capillaries open in any territory at a given moment is dependent on the activity of the tissues. If the capillaries of a resting muscle are made visible by injecting India ink, very few of them are seen, and these are of small diameter. When the experiment is repeated in a muscle stimulated by a tetanizing current, the number of visible capillaries increases tenfold, or even more, and their diameters are considerably larger (Krogh) (Fig. 118). The increase of blood flowing through the muscles is compensated by simultaneous vasoconstriction in other territories.

Fig. 118. Diagram of capillaries in the muscles of a guinea pig injected with India ink. From left to right: resting muscle, 200 open capillaries per square millimeter; after moderate exercise, 700 open capillaries per square millimeter; after intense exercise, 2,500 open capillaries per square millimeter. (*After Krogh.*)

Many factors cause the opening and closure of the capillaries.

When the capillaries of an organ dilate, the organ increases its volume but there is no significant change in arterial blood pressure, because peripheral resistance is caused mainly by arteriolar constriction, and cannot therefore be modified to any extent by a dilatation occurring downstream with respect to the arterioles.

Nervous factors. In the frog, stimulation of the sympathetic nerves causes capillary constriction, even when the circulation has been stopped by extirpation of the heart. The capillary constriction is therefore an active phenomenon. Stimulation of the cervical sympathetic in the rabbit produces constriction of the capillaries in the ear of the same side, even when the circulation has been arrested by occlusion of the artery. On the other hand, centrifugal stimulation of the dorsal spinal roots in the frog causes capillary dilatation in the

corresponding territory, even when the arteries have already been maximally dilated by an injection of acetylcholine.[1] In this case dilatation cannot have been a passive result of an increase in capillary blood pressure. The effects of nerve stimulation (sympathetic nerves and dorsal roots) are therefore in the same direction in the capillaries as in the arteries.

Humoral factors. Local capillary dilatation occurring in the course of activity may be caused by substances resulting from the increased metabolism of the tissue. Sometimes they act by modifying the local acid-base equilibrium, *i.e.*, CO_2 and other metabolites lower the pH. Other substances act through a different mechanism. Thus histamine, which is a powerful capillary dilator, is released whenever cells are damaged. Several of the responses observed in the skin capillaries have been attributed to the release of histamine or histaminelike substances (Lewis's H substance).

Several hormones play a part in the control of capillary diameter. Adrenaline and pituitrin exert a marked constrictor effect.

Response of the cutaneous capillaries. The color of the skin. The color of the skin is fundamentally due to melanin, a black pigment found in the pigment cells of the epidermis. A striking characteristic of the white race is the small amount of melanin in its skin; consequently in that race the vessels of the dermis (arterioles, capillaries, and venules) play an important part in giving the skin its color. Through the translucent layers of the epidermis the color of the blood contributes to the color of the skin, according to the number and diameter of the blood vessels and the color of the blood in them. Normally the color is pale pink.

When the concentration of nonoxygenated hemoglobin in the capillary blood rises above 5 gm. per 100 cc., the skin takes on a bluish color, and the condition is known as cyanosis. Methemoglobin (intoxication by nitrites or bismuth subnitrate) and sulfhemoglobin (absorption of sulfur compounds produced by intestinal bacteria) also give the skin a blue color. Accumulation of bilirubin in the blood near or over 20 mg. per liter (normally there is about 6 mg. per liter) confers a yellow tinge to the skin, and the condition is known as jaundice. The intensity of the yellow tinge increases with the concentration of bilirubin in the blood.

[1] Doi, V., *J. Physiol.*, 54, 227, 1920.

Changes in diameter of cutaneous blood vessels modify the color and temperature of the skin. The color is influenced principally by the degree of dilatation of the capillaries and by the color of their contents. The temperature is conditioned by the volume flow, which is controlled by the diameter of the arterioles. A pink, warm skin means arteriolar and capillary dilatation. A pale, warm skin is due to dilated arterioles and constricted capillaries. A pale, cold skin means that arterioles and capillaries are constricted. In very cold weather the exposed skin is cold and blue. In this case the arterioles are constricted and the blood flow is slowed down in dilated capillaries; consequently more oxyhemoglobin is changed to nonoxygenated hemoglobin than when the circulation is more active. Venous obstruction causes cyanosis by a similar mechanism; passive capillary dilatation enhances the bluish tinge of the skin.

DERMOGRAPHISM

The white line.[1] If the skin is stroked with a blunt object without exerting too much pressure, a white line appears gradually, exactly limited to the area stimulated. It lasts for a few minutes and then disappears. This is a normal response, more marked in some subjects than others. The skin of the body, which is less pigmented, usually gives a more visible line than that of the limbs. Microscopic observation shows the white line to be due to local constriction of the capillaries. If the arterioles were also constricted, the contour of the line would not be clearly and exactly limited to the area stimulated, because arterioles supply an irregular area of the skin. The response is observed even when the arteries have been previously occluded or the nerves severed.

The triple response.[2] In sensitive subjects, or when a stronger stimulus (heavy stroking) is applied, the response takes place in three stages.

1. *The red line.* After a short latent period, a red line appears, exactly limited to the area stimulated. It gradually becomes cyanotic because oxyhemoglobin in the stagnated capillary blood is reduced more than normally. The red line is due to capillary dilatation and is observed even in denervated areas.
2. *Erythema or flare.* After a further delay of 15

[1] Cotton, T. F., J. G. Slade, and T. Lewis, *Heart*, **6**, 227, 1917.

[2] Lewis, T., *Heart*, **11**, 109, 1924.

to 30 sec., especially in sensitive subjects, around the red line an erythematous area appears. This flare is due to arteriolar dilatation; its borders are irregular, and the color is not uniform in all the flushed skin. It does not become cyanotic, because the arteriolar dilatation maintains an active circulation through the capillaries. The temperature of the flushed skin rises. Flare is not observed in denervated areas, but cocainization of the nerve trunk does not suppress it, because it is due to an axon reflex.

3. *Wheal.* In especially sensitive subjects a wheal develops over the red line. This wheal projects 1 to 2 mm. above the normal skin and reaches a maximum in about 5 min. Whealing is due to the escape of fluid through the capillary walls. The fluid is similar to blood plasma; it has 4 to 5 per cent protein, with traces of fibrinogen, and it clots when shed. This abnormal passage of fluid from the blood to the tissues is caused by an abnormally increased permeability of the capillary wall.

Action of histamine. Lewis demonstrated that intradermal injection of histamine (diluted 1:3,000) provokes the same triple response as heavy stroking of the skin; *i.e.*, red line due to local capillary dilatation, flare caused by arteriolar dilatation, and wheal due to increased exudation of fluid. The time relations are the same in both cases. This fact suggested that the triple response is due to local release of histamine or of a substance similar to histamine called "H substance" by Lewis.

The triple response can be evoked by many agents: tickling, scratching, freezing, and burning of the skin, electric stimulation, local application of caustic and other substances such as atropine, cantharidin, peptone, allergens, etc. In all these cases there is damage to the cells, and the most plausible explanation is that this causes liberation of a substance (histamine or H substance) that provokes the triple response.

Significance of the triple response. Lewis and his associates have carefully examined the vascular reponses of the skin to the application of external stimuli. They constitute a local, and more or less intense, expression of the more general process known as inflammation. The three stages (triple response) are observed in especially sensitive subjects, or when the stimulus is sufficiently strong; but the response can vary in extension and degree. It is not always as typical as the description given here.

The epidermis clearly plays a protective role. The response is less marked where the epidermis is particularly developed, *e.g.*, on the palms of the hands or soles of the feet. If stimulation is repeated a sufficient number of times over the same area, vascular reactions are followed by proliferation of the epidermis with formation of callosities (corns).

CAPILLARY PERMEABILITY

Exchange of substances between the blood and tissue fluids. The blood vessels form a system of completely closed tubes. The walls of these tubes vary in thickness, but however thin they are they can always be recognized. The blood is never in direct contact with the cells nor does it mix with the tissue fluids. Only in the liver and in the spleen are there special capillaries known as sinusoids, the very thin walls of which seem to be missing in parts, so that the hepatic and splenic cells themselves form the walls of the blood vessel.[1] The usual structure, nevertheless, is such that substances brought by the blood to the tissues must pass through the capillary walls to mix with the tissue fluids, and substances eliminated by the cells into the tissue fluids must also pass through the capillary walls to be taken up by the blood. The mechanisms by which substances pass through the capillary walls and the different factors that condition this passage are still insufficiently known. They are essentially processes of filtration[2] and diffusion[3] through the capillary membrane which take place simultaneously. Factors in these processes are the following: (*a*) the capillary membrane; (*b*) the hydrostatic pressures within and without the capillary; (*c*) the physicochemical condition and concentration of the substances in the blood and tissue fluids.

[1] The absence of a wall in the hepatic and splenic sinusoids is not universally admitted.

[2] Filtration is the passage through a membrane of a solvent, and the substances dissolved, caused by a difference in the hydrostatic pressure on each side of the membrane. When only substances in true solution pass and substances in a colloid dispersion are retained, the term used is ultrafiltration.

[3] Diffusion (dialysis) is the passage of a substance through a membrane caused by a difference in the concentration of the substance on each side of the membrane. The substance always passes from the higher to the lower concentration.

The *capillary wall* is functionally complex, and because of this complexity, it has not yet been possible to make a direct analysis of the phenomena taking place in the membrane. The membrane is permeable to water and substances in true solution both from the blood to the tissue fluid and vice versa. Passage of these substances may be interpreted as if it were a process of filtration. The characteristics of the filtrate demonstrate that the "pores" of the membrane are sufficiently small to prevent the passage of protein molecules and, of course, of the blood cells. The white cells pass through the capillary walls and migrate to the tissues by special movements of the cells (diapedesis).

The size of the "pores" of the capillary membrane depends on its nutritive conditions. The permeability of the capillary walls is definitely influenced by anoxia, endocrine secretions, drugs, toxins, etc. Anoxia increases permeability to the extent of allowing the protein molecules to pass out of the capillaries into the tissue fluid. The internal secretion of the adrenal cortex, or an increase in Ca^{++} ion concentration in the blood, onahe contrary, diminishes permeability to water nd certain salts. A very marked increase in permeability is observed in cases of extensive burns, because of the reabsorption of substances from the damaged tissues. The loss of fluid through the capillary wall in these cases is such that the circulating blood volume may diminish considerably; in some cases to such an extent that the life of the patient may be in danger.

Hyaluronic acid in the connective-tissue matrix is also a structural component of the capillary wall, more especially of the pericapillary sustaining sheath. Hyaluronidase, an enzyme which hydrolyzes hyaluronic acid, acts by increasing capillary fragility and facilitating the rupture of these vessels, rather than as a controlling factor in capillary permeability.[1]

Chambers and Zweifach,[2] through ingenious experiments, demonstrated that filtration takes place through the intercellular cement and that proteins that are too large to pass obstruct the passages in the cement. Factors influencing permeability, according to these observers, modify intercellular cement by contributing to its formation or destruction or by changing its consistency.

The hydrostatic pressure necessary for filtration results from the difference between the blood pressure in the capillaries and the pressure of the tissue fluids. Plasma proteins are hydrophil colloids, which, beside the osmotic pressure exerted by their molecules, have an imbibition pressure; the sum of both is the oncotic pressure. The balance between hydrostatic pressures within and without the capillary and the oncotic pressure of the plasma proteins will condition filtration and the direction in which it takes place. Vasomotor acitivity of the metarterioles and the precapillaries exerts considerable influence on the pressure and velocity of flow in the capillary system, and therefore on the exchange of fluid between the capillaries and the surrounding tissues. Thus, when the muscles of the metarterioles and precapillaries are relaxed, the precapillaries are open and the pressure transmitted by the arteries is spread over the whole capillary network. The speed of flow diminishes considerably in the capillaries and in the preferential channels, so there is a tendency to stagnation in the collecting venules. Intravascular pressure rises, and outward filtration is facilitated. On the other hand, when the metarteriole and precapillary muscles are active, the flow of blood into the capillaries is progressively restricted and eventually takes place only along the preferential channels, coursing rapidly to the venules, and pressure conditions become favorable for inward filtration, *i.e.*, passage of fluid from the tissues into the capillaries.

The nature and concentration of the substances in the blood and tissue fluids are of considerable importance in the interchanges through the capillary walls. The part played by the proteins, as already seen, is a major one. If the concentration of plasma proteins is decreased (*e.g.*, by endovenous injection of saline solutions or of solutions of other crystalloids) the oncotic pressure decreases, the effective filtration pressure increases, and more fluid passes out into the tissues. Fluid thus injected into the blood rapidly escapes from the blood vessels; it is useless to endeavor to increase the blood volume by this kind of treatment. To accomplish that objective a hydrophil colloid, incapable of diffusing out of the capillaries, must be used. The best procedure, however, is to transfuse blood, blood

[1] Zweifach, B. W., and R. Chambers, *Ann. New York Acad. Sc.*, **52**, 1047, 1950.

[2] Chambers, R., and B. W. Zweifach, *J. Cell. & Comp. Physiol.*, **15**, 255, 1940.

plasma, or dried blood plasma redissolved in water.

Plasma-protein concentration may diminish either because of insufficient formation, as occurs when there are certain deficiencies in the diet, or because proteins are lost through the kidneys, as in certain cases of renal disease (nephrosis) in which large amounts of serum albumin pass into the urine (albuminuria). The oncotic pressure diminishes in all these cases, and consequently filtration out of the capillaries increases (see "Edema," further on).

Plasma proteins play their part in the process of capillary filtration because (*a*) they are hydrophilic; (*b*) they do not pass through the pores of the capillary membrane; (*c*) the protein content of the tissue fluids is far below that of blood plasma. If protein concentration were the same in tissue fluids as in blood plasma, the oncotic pressure would no longer be a factor in capillary filtration.

Serum albumin is the most important of the plasma proteins in this respect, because it has a smaller molecule and therefore a larger number of molecules per unit weight than the other proteins. The oncotic pressure (imbibition plus osmotic pressure) will be greater the larger the number of molecules in unit volume (molecular concentration).

If hemoglobin were free in the plasma instead of being enclosed in the erythrocytes, owing to its hydrophilia it would exert an oncotic pressure sufficient to annul the hydrostatic (blood) pressure in the capillaries and filtration would not be possible. This is one of the many advantages to the organism of having hemoglobin in the red cells. Hemocyanin, the respiratory pigment of some invertebrates, has a very large molecule (molecular weight 5,000,000) and therefore exerts only a weak oncotic pressure; it can thus be dissolved in the blood plasma without disturbing capillary filtration.

Crystalloids diffuse rapidly through the capillary membrane, so it is difficult to maintain different concentrations on each side of this membrane for any length of time. They have only transitory effects on the movement of fluids from the blood to the tissues and vice versa. Crystalloids pass to and from the tissues by dialysis or are carried in the flow of water.

Consequences of capillary permeability. The formation of lymph. There is a continuous flow of substances from the blood to the tissues and back from the tissues to the blood. When an organ is at rest and the number of open capillaries is small, the mass of substances transported from the blood to the tissues is approximately the same as that from the tissues to the blood. When an organ becomes active the number of open capillaries is greater, and the blood pressure and flow increase in them. When this occurs the outflow from the blood into the tissues is greater than the inflow in the opposite direction. The balance of fluid and substances is drained by another route. If the organ is a gland with external secretion, this may be excreted by the glandular duct. If the tissue is not a gland of this nature, the excess of substances that cannot be reabsorbed into the capillaries is drained by a special system of closed vessels, called the lymphatics, which have no direct communication with the tissue fluids. They join to form vessels of increasing diameter and eventually end in the large veins near the heart.

In the glomeruli of the kidney the capillary filtrate (glomerular filtrate) is collected by a system of tubes (renal tubes), and part of it is excreted outside the body in the form of urine after having undergone important changes by reabsorption of some substances and addition of others (see Chap. 63).

Edema. Abnormal accumulation of fluid in the tissues is known as edema. It frequently occurs in and under the skin where it can be the subject of direct observation. An edematous skin appears swollen; normal dimples, folds, and wrinkles are less conspicuous. When pressure is exerted with the finger, the skin and tissues do not give the sensation of elastic resistance, and as the fluid is displaced a depression or "pit" remains. In some cases edema spreads to many tissues, and the excess fluid is attracted by the force of gravity to the dependent parts where edema is thus more marked. In generalized edema sometimes the internal cavities, pericardium, pleura, and peritoneum are filled with fluid. This condition is known as dropsy or anasarca. The body weight increases in proportion to the amount of fluid accumulated.

Not only water, but also salts, especially sodium chloride, are retained in the organism, because edematous fluid is isotonic with the blood plasma. Reciprocally, retention of salt causes the accumulation of water, so that diets with little or no sodium chloride hinder the formation of edema and facilitate its reabsorption.

Ion-exchange resins[1] have an interesting effect on edema. In the acid form these resins take up Na^+, K^+, Ca^{++} and other inorganic and organic cations. This combination takes place in the intestine of subjects who have ingested them, and not only the cations in the food but also those in the body tissues are combined and eliminated with the resin. In cases of edema the resins are given in order to prevent absorption of sodium (sodium chloride can thus be added to food for its savory properties) and to withdraw sodium (and therefore water) stored in edema. Synthetic resins derived from polystyrene with crossed di-vynil benzene bonds are used. It must be remembered that their action is not specific for any particular cation; they bind all of them, and so they may provoke deficiencies in K^+, Ca^{++}, or Mg^{++} or acidosis.

There are many causes of edema, and in some cases more than one plays a part; in all of them there is an insufficient reabsorption of fluid from the tissues.

Stasis due to venous obstruction or heart failure increases capillary pressure and therefore also the effective filtration pressure. This is not the only cause of edema in such conditions. Anoxia and accumulation of metabolic products due to incomplete oxidation and impaired circulation, by increasing capillary permeability, also contribute to produce edema.

Renal disturbances cause edema through several mechanisms. In cases of nephrosis because of the marked albuminuria, the plasma protein concentration diminishes, and the oncotic pressure decreases; therefore the increased effective filtration pressure drives a greater amount of fluid out of the capillaries. A similar condition can be produced experimentally in animals by plasmapheresis: blood is drawn, and the erythrocytes suspended in saline are reinjected. If this procedure is repeated several times, the plasma protein concentration is significantly lowered and edema results. When the plasma proteins are restored to their normal concentration, edema disappears. In cases of glomerulonephritis, water, salts, and nitrogenous substances are retained; this together with loss of plasma protein by albuminuria produces edema.

Nutritional edema is observed when a qualitatively or quantitatively insufficient diet causes hypoproteinemia. Hypoproteinemia is not, however, always the cause of nutritional edema. In these cases, as in others in which there are cachectic conditions, the pathogenesis of edema is obscure.

Lymphatic obstruction produces edema in the territories normally drained by the obstructed lymphatic vessels. It may be caused by parasites (filariasis, elephantiasis), tumors, etc.

[1] Dock, W., *Am. Heart J.*, **40**, 638, 1950.

Inflammatory edema is due to increased capillary permeability produced by the toxic substances that cause the inflammatory process (bacterial toxins, venoms, caustic substances, etc.) or by substances discharged by the cells when damaged (traumatism, several physical agents such as heat, cold, sunlight, etc.). These substances are histamine or similar to histamine (see "Action of histamine," page 214). The intensity of the process of increased permeability and the area to which it extends vary according to the causative agent. In some cases there is simply an increased transudation of normal fluid; in others the fluid shed has a high protein content, and even fibrinogen may filter through the capillary membrane. All the intermediate conditions are possible between these extremes.

Capillary fragility. The resistance of the capillaries to mechanical force acting on them varies in different subjects and in the same subject in different circumstances. In some cases the slightest trauma, such as moderate pressure on the skin, or the small increase in capillary blood pressure caused by coughing, or a bodily effort, provokes the rupture of the capillaries. Blood seeps into the tissues, a hematoma is formed, and the hemoglobin suffers a series of chemical changes that provoke marked discoloration in the bruised area; finally the blood is reabsorbed.

Capillary resistance to mechanical agents diminishes considerably in certain pathologic conditions, *e.g.*, scurvy. Vitamin C, the lack of which causes scurvy, has therefore been thought to be an important factor in the prevention of capillary fragility. More recently, vitamin P (citrine) and rutine,[1] a flavonol glycoside, have been considered necessary factors for the maintenance of capillary resistance (see Chap. 49).

There are several methods for determining capillary resistance. They are based on two general principles:

1. Capillary pressure is increased by applying an external pressure sufficient to suppress the venous circulation, but not enough to occlude the arteries, so that blood will continue to flow into the capillaries (a sphygmomanometer is used).

[1] Griffith, J. Q., J. F. Couch, and M. A. Lindauer, *Proc. Soc. Exper. Biol. & Med.*, **55**, 228, 1944; Scarborough, H., *Biochem. J.*, **39**, 271, 1945; Shanno, R. L., *Am. J. M. Sc.*, **211**, 539, 1946.

2. The pressure in the tissues surrounding the capillaries is reduced by means of a suction chamber (*e.g.*, cupping).

Tey[1] found a close relationship between the pressures that provoke the rupture of the capillaries and the arterial blood pressure. Capillary fragility is normal when the aspiration pressure must be kept for 5 min. at more than 60 mm. (at least 40 mm.) above the systolic pressure in order to produce moderate hemorrhagic spotting of the skin. It is subnormal when an aspiration pressure of 20 to 40 mm. above the systolic pressure produces this effect, and it is pathologic when hemorrhagic spotting occurs with even lower aspiration pressures. He found that sodium, potassium, and calcium have no effect on capillary fragility, that adrenaline reduces it for a very short time, and that histamine increases it. Again according to Tey, vitamin C diminishes an already increased capillary fragility in some cases but not in others.

[1] Tey, A., "Fragilidad Capilar Normal Humana," Espasa-Calpe, Barcelona and Buenos Aires, 1940.

TRAUMATIC SHOCK

Traumatic shock is characterized by a deep, generalized functional depression following extensive damage to the tissues. It is called "primary shock" when it occurs immediately after the trauma, and "secondary shock" when it appears only after an interval of several hours.

The exact mechanism leading to shock, especially to secondary shock, is still under discussion. When shock has developed, characteristic blood changes and circulatory disturbances are observed. The capillaries play a fundamental part in the mechanism of shock, and for this reason the condition is considered in this chapter.

The blood shows an increase in concentration (hemoconcentration). This causes an increase in the red cell count and volume, in hemoglobin concentration, in the white count, and in the specific gravity of the whole blood. Plasma proteins and nonprotein nitrogen also increase. The condition is one of anhydremia (loss of water from the blood). In cases with profuse hemorrhage blood concentration is sometimes masked by compensatory reabsorption of tissue fluids.

There are considerable disturbances in the circulation. Arterial blood pressure falls to a low level and the volume flow diminishes. It has been definitely proved this is not due to central circulatory insufficiency (heart failure). The fundamental properties of the myocardium are normal, but because the venous return is considerably reduced, the heart does not eject at each systole a sufficient amount of blood to maintain the arterial pressure.

There is peripheral circulatory insufficiency.[1] Arterial hypotension and the diminished volume flow are not due to arterial vasodilatation; on the contrary, the arteries are constricted. Arterial constriction is a compensatory response to hypotension, produced by a reflex starting in the cardioaortic and carotid pressoreceptors. Tachycardia—always observed in shock—has the same origin. Increased sympathicoadrenal activity is thus a compensatory response to hypotension; nevertheless it can increase the severity of shock because it ultimately reduces the mass of circulating blood.[2] Circulatory insufficiency is due to hypovolemia, caused mainly by anhydremia produced by the escape of fluid brought about by an increase in permeability of the capillary walls. Hemorrhage, if it has occurred, accentuates hypovolemia, but even in cases in which there has been no hemorrhage, severe hypovolemia can be observed. In cases without hemorrhage, hypovolemia is caused exclusively by the loss of fluid due to increased capillary permeability. As time passes this disturbance becomes more marked and is finally irreversible.[3]

In experimental shock provoked by hemorrhage in the dog, Shorr, Zweifach, and their associates[4] have distinguished a hyperreactive from a hyporeactive phase. During the former a vasoexcitor material (VEM) appeared in the blood. This substance was demonstrated by injecting it intravenously into rats and observing the sensitizing effect it had on the response to adrenaline by the blood vessels of the meso-appendix. When hemorrhage caused severe hypotension, release of VEM diminished simultaneously with the decrease in renal blood flow, and the hyperreactive phase ended. This phase could not be demonstrated in animals with the kidneys excluded from the circulation by tying the renal vessels. During the hyporeactive phase the liver, and in a lesser degree the spleen and skeletal muscles, released a vasodepressor material (VDM). *In vitro* experiments showed that both substances were formed in response to anoxia. VDM has been identified with ferritin, or its iron-free derivative, apoferritin.

Treatment of shock must be directed in the first place to the restitution of the circulating blood volume with the least possible delay. Intravenous injections of saline or gum acacia are no longer used because they give only transitory and inconstant results. Transfusion of whole blood or plasma, according to the degree of hemoconcentration, must be performed as soon as possible. Shock should be prevented by appropriate measures, and constant vigilance exercised to recognize the initial signs and symptoms (hypotension, progressive tachycardia, hemoconcentration) as soon as they appear. The physician should keep in mind that treatment is very effective for the prevention of shock or in the first stages; later, when the condition has progressed to a certain degree of severity, it becomes irreversible and treatment is no longer effective.

Blood changes and hemodynamic conditions in the principal types of shock. Richards,[1] after careful observation of the blood changes and hemodynamic conditions in different types of shock, has summarized his conclusions as follows:

1. *Secondary traumatic or hemorrhagic shock.* Total blood volume diminished; loss of erythrocytes greater than loss of plasma; venous return diminished; minute volume diminished; arterial blood pressure decreased; intra-auricular pressure decreased; peripheral resistance diminished.
2. *Shock due to burns.* Total blood volume diminished; hemoconcentration; minute volume diminished; arterial blood pressure normal or high; intra-auricular pressure normal or high; peripheral resistance increased. Transfusion of plasma causes a rapid fall of intra-auricular pressure.
3. *Medical shock (pneumonia, sepsis).* Total blood volume normal; minute volume diminished; arterial blood pressure decreased (vasomotor collapse).
4. *Neurogenic or primary shock (syncope).* Peripheral resistance diminished.

[1] Richards, D. W., *Bull. New York Acad. Med.*, **22**, 630, 1946.

Peripheral resistance can be quantitatively gauged, with satisfactory approximation, by dividing the mean arterial pressure by the minute volume. Normal resting subjects have a mean blood pressure of 90 mm. Hg and a minute volume of 5.4 liters; peripheral resistance is therefore equal to 16.

CHAPTER 23

Circulation in the Veins

AFTER THE BLOOD leaves the capillaries, it flows through the veins. These are converging tubes, arising in all the tissues, and ending in the right auricle by means of two main collecting trunks. This is the general venous system, which corresponds to the aortic system. In the pulmonary system the veins arising in the lung capillaries converge to main trunks ending in the left auricle.

The venous tubes have fibromuscular walls, which are flaccid and collapsible; they increase in diameter as they approach the heart. A prominent and important feature is the existence of valves, placed so that blood can flow only toward the heart. The valves were discovered by Fabritius of Acquapendente[1] in 1574, but their functional significance was not understood until Harvey demonstrated it in 1628.

The veins are formed by a thin wall of fibrous tissue, with few elastic and muscle fibers. The inner aspect of the veins is completely lined by endothelium. The valves are formed mainly by a fold in the endothelium.

Veins are clearly different from arteries, not only in structure but also in other respects. The ratio between the diameter of the vessel and the thickness of its wall is much greater in the veins than in the arteries. Distensibility is different in each type of vessel. An increase in internal pressure rapidly increases the capacity of the veins, but a further increase in pressure rapidly causes maximum distention. Arteries are relatively more distensible than veins. Roy[2] observed that in order to double the capacity of a vein the internal pressure must be raised from 0 to 500 mm. of water. The blood in a dilated vein therefore is not necessarily at high pressure. As the pressure in the large cervical and thoracic veins never reaches 500 mm. of water (the pressure necessary to double their capacity), changes in volume are due to variations in blood mass more than in pressure.

The muscles of the veins are functionally important. If they contract, the diameter and capacity of the veins diminish, and sometimes considerably. These muscles are under nervous control, but humoral, mechanical, and other stimuli acting locally also modify their activity. The large veins near the heart show rhythmic contractions of their walls, synchronous with the heartbeat. In certain animals other veins also contract rhythmically, *e.g.*, those in the wings of the bat.

Venous blood pressure. Direct manometric measurements of venous blood pressure give the most accurate results. The cannula should be placed in the vein without obstructing the blood flow, because the lateral and not the end pressure is important. If the vein is obstructed, blood is dammed up and the pressure rises until it can flow through collateral veins. There is a considerable rise in venous pressure when the principal vein of a large area is closed, *e.g.*, when the principal vein of a limb is tied venous pressure rises up to the level of the mean arterial pressure. To avoid this, T cannulas are used. In the large veins needles can be thrust through the wall. Although the needles must be of sufficiently large bore they must not completely obstruct the vein. A system of tubes connects the cannula or the needle with a water manometer or with an aneroid manometer calibrated in millimeters of water. Burch and Winsor s aneroid flebomanometer[1] is easy to handle and a useful, practical instrument.

The vein chosen for the determination of the venous blood pressure should be at approximately the same level as the right auricle. If it lies above this level, the effect of gravity will tend to empty the vein and lower readings than the true ones will be obtained; whereas if it is below, the hydrostatic pressure of the column of blood between the auricular level and the cannula will be added.

Table 18 gives the average venous pressure in several territories of normal subjects; there are considerable individual variations. Venous pressure is not related to age or race; the figures found in women are, however, somewhat higher than those found in men.[1]

Venous pressure can be measured in human beings with no discomfort by resorting to indirect methods based on Von Recklinghausen's method.[2] In this method a cutaneous vein is compressed through the skin by a pneumatic rubber ring, connected to a water manometer and an insufflator. The ring is kept in place by a glass plate through which the exact moment the vein collapses can be noted. The minimum pressure necessary to bring about this collapse is equivalent to the venous pressure. Neither this method nor its modifications give precise results; moreover, they can be applied to only a few venous areas.

An approximate idea of venous pressure can be obtained by very simple procedures. If the subject is lying on his back with his head slightly raised, the jugular vein acts as a manometer. In normal conditions it appears distended up to 1 or 2 mm. above the clavicle. Another method (Gärtner)[3] is to raise passively the hand of a seated subject and observe the exact level at which the veins of the back of the hand collapse. The difference in height between this level and the sternocostal angle (the level of the heart) gives the venous pressure in millimeters of blood (approximately equivalent to millimeters of water) in the veins of the back of the hand. This pressure is normally from 80 to 120 mm.

Venous pressure diminishes progressively from the capillaries to the right auricle. This pressure difference is the principal cause of the

movement of the blood from the capillaries to the heart. It is normally maintained by the activity of the heart, which is the cause of the pressure in the capillaries, and by the thoracic "negative" pressure. The effective pressure for venous circulation can be maintained, in normal and in pathologic conditions, by pressure changes in the initial (capillary) and final (thoracic) portions of the system. If thoracic pressure is raised by keeping the glottis closed during forced expiration (Valsalva's experiment), this increases the end pressure in the venous system; automatically stasis is produced and the capillary pressure increases, thus restoring the effective pressure needed to keep the venous blood circulating toward the heart. Pulmonary emphysema causes permanently similar conditions. The muscles of the veins can also participate in adjusting the effective pressure.

Posture and exercise have a marked effect on venous pressure. In a series of observations the average venous pressure at the ankle was found to be 11.7, 56.0, and 86.8 mm. H_2O with the subject lying down, sitting, and standing up respectively. Walking caused an appreciable decrease in the venous pressure with respect to its value when the subject was standing still. During the first 3 to 12 paces, venous pressure fell. It then remained stationary at average levels of 22.3, 24.3, and 23.6 mm. H_2O when the subject was walking at 1.7, 2.6, and 3.3 miles/hr. respectively, remaining at this level for the rest of the walk. The level of stabilization was not therefore influenced by the speed of walking. When walking ceased the venous pressure returned to the initial level in ½ min.[1]

Venous pressure gives valuable information to the physician in certain circulatory disturbances, but the influence of variations in intrathoracic pressure and other extracirculatory factors must first be excluded. For example, pulmonary emphysema causes venous hypertension by the mechanism explained above, and mediastinal tumors increase venous pressure by compression and obstruction of the large thoracic veins.

In circulatory failure of central origin, *i.e.*, caused by heart insufficiency, venous pressure is increased. In peripheral circulatory failure (hemorrhage, arterial vasodilatation, capillary hypotonia, shock, etc.) venous pressure falls.

[1] POLLACK, A. A., and E. H. WOOD, *J. Applied Physiol.*, 1, 649, 1949.

Velocity of blood flow in the veins. Velocity of flow in the veins is measured by the same methods as velocity of arterial flow. In experimental animals it has been found to be constant in peripheral veins and to fluctuate in the veins near the heart. Velocity of flow increases from the periphery to the heart, because of the progressive decrease in total cross-sectional area. In the large venous trunks, variations in intrathoracic pressure produced by respiratory movements and the cardiac cycle are responsible for periodic changes in the velocity of flow. The combined effects of all these factors produce changes in volume in the cervical veins, which are easily seen in subjects lying down; this is the venous pulse, which will be examined in detail further on, because of its physiological and medical importance. Fleck[1] measured the velocity of flow in the external jugular vein of dogs by means of a hemotachometer with optic registration. The volume flow as 78.7 cc. per min. during inspiration and 89.2 cc. during expiration, and the respective velocities 215 and 243.5 mm. per sec. In the superior vena cava the volume flow was 395 cc. per min. during expiration and 485.7 cc. during inspiration; and the velocities 183 and 224 mm. per sec. Maximum acceleration and increase in blood flow were observed at the end of inspiration. The maximum reduction in flow and velocity occurred immediately before inspiration. Cardiac activity causes fluctuations of lesser amplitude than the respiratory variations.

The speed of flow in the veins can be measured in man by injecting a radioactive sodium isotope (Na^{24}) into a dorsal metatarsal vein and recording its arrival at the groin by means of a Geiger-Müller counter. The average time in healthy individuals has been found to be 18 ± 0.9 sec., with a range from 4 to 50 sec.[2]

Factors that influence venous blood flow. The principal cause of the movement of the venous blood is the difference in the pressures in the capillaries and in the auricle. This effective pressure is due in the first place to the activity of the heart, which is therefore the efficient cause of the venous return. There are other accessory factors, such as the negative intrathoracic pressure, which also contribute to the venous circulation. Inspiration increases the

[1] FLECK, S., *Ztschr. f. Kreislauff.*, 25, 504, 1934.
[2] WRIGHT, H. P., S. B. OSBORN, and D. G. EDMONDS, *Lancet*, 2, 767, 1948.

"negative" thoracic pressure and expiration decreases it, but in any case this factor is of secondary importance. The heart also exerts a certain sucking effect on the blood of the veins at the beginning of auricular diastole and during the phases of ejection and of rapid filling of the ventricle.

Venous circulation is also influenced by local and general variations in the capacity of the venous system. These variations are due to contraction and relaxation of the venous muscles and to changes in the circulating blood volume. Widespread venous constriction and an increase in blood volume increase the venous return, and vice versa.

Hydrostatic pressure due to gravity acts differently according to the position of the subject and the venous territory considered. In a man standing at ease, gravity is a positive factor in the circulation in nearly all the territory drained by the superior vena cava, and a negative factor in the territory of the inferior vena cava. The negative effect of gravity is antagonized to a certain extent by the venous valves, the vasomotor responses of the venous muscles, and the contraction of skeletal muscles.

The effect of muscular contraction is clearly demonstrated in the following observation made by Atzler and Herbst:[1] if a subject is sitting with his legs hanging loosely, the muscles being relaxed, the volume of the lower part of both legs increases 1.1 per cent in 1 hr.; if he is standing up, the volume increases 3.6 per cent; but if he is walking, the increase is only 1.99 per cent. The increase in volume is due to venous stasis which raises the capillary pressure and causes a greater filtration of fluid from the blood to the tissues. When the muscles contract they press on the veins and empty them; the venous valves direct the flow toward the heart.

Special adaptation reactions take place in abnormal conditions. If the heartbeat weakens or ceases, venous circulation does not stop immediately, even if the arterial pressure falls to zero. This is observed when the heart is stopped by stimulation of the vagus nerve and in ventricular fibrillation. In both cases the heart dilates progressively because its contents continue to increase, and the veins near the heart show considerable engorgement. If an opening is made in the heart or the vena cava, blood flows copiously and more than 50 per cent of the blood volume can be collected in this way, in spite of the nonexistence of the heartbeat. Henderson attributes this flow to the tone of skeletal muscles. It is quite probable, however, that the muscles of the veins, stimulated directly (anoxia) or reflexly (arterial hypotension acting on the cardioaortic and carotid sinus, pressoreceptors) play an important role. Whatever its immediate cause, this mechanism is a safety factor when the heartbeat weakens, because the increase in venous flow and pressure assures the filling of the heart and the increase of initial pressure, which, according to Starling's law, will increase the force of myocardiac contraction. Venous hypertension observed in the first stages of central circulatory insufficiency is due to the same mechanism.

[1] ATZLER, E., and E. HERBST, *Ztschr. f. d. ges. exper. Med.*, **38**, 137, 1923.

THE VENOUS PULSE

Variations in intrathoracic pressure caused by respiratory movements, and changes in intra-auricular pressure in the course of the cardiac cycle, determine fluctuations in the velocity of flow in the large venous trunks near the heart. Changes in volume in the cervical veins thus occur and can be easily seen in recumbent subjects. These changes in volume are the cause of the venous, or jugular, pulse. There is therefore a respiratory venous pulsation and a cardiac venous pulsation. Usually by "venous pulse" is meant the pulsation of cardiac origin, which is of great physiological and medical importance.

Hunter (1794) was the first to observe the venous pulse, which was graphically registered for the first time by Friedereich in 1866. Potain, Marey, Mackenzie, Wenkebach, Ohm, and Wiggers used successively more accurate and sensitive methods of registration and were thus able to establish the nature and significance of the venous pulse in normal and pathologic conditions. Registration of the venous pulse is now commonly used in the interpretation of many aspects of normal and abnormal cardiac function.

The phlebogram. This is the name given to the record of the venous pulse. A small funnel (which is sometimes covered by a very thin rubber membrane) is placed over the external jugular vein in the supraclavicular fossa, exerting slight pressure so as to assure perfect contact between the skin and the entire edge of the funnel. Changes in venous volume are trans-

mitted by a system of rubber tubes to a Marey tambour (registration on a smoked surface) or a Frank segment capsule (optical registration). Optical registration is preferable because records obtained on a smoked surface are deficient in many respects. The subject must be lying down,
Fig. 119. "Pure" venous pulse. Phlebogram, phonocardiogram, and ECG; simultaneous records obtained from a normal man. The *c* wave is of small amplitude. (*Caeiro, 1942.*)

to avoid the effect of gravity which tends to empty the vein and diminish the amplitude of the venous pulse. The head should be resting comfortably, so as to obtain complete muscular relaxation, and should not be turned to the opposite side.

At each cardiac cycle the normal phlebogram constantly shows three main waves and two depressions[1] (Figs. 28, 39, 40, 45, 46, 113, 114, 119, 120). These features have been given different names. Mackenzie's terminology has been generally adopted; he named the main waves *a*, *c*, and *v*, in the order of their appearance in the cardiac cycle, because the first one was attributed to the auricle, the second to the carotid, and the third to the ventricle. The depressions were called *x* and *y*. In a long cycle sometimes a fourth wave (*h*) is observed.

Optical registration, because of its high natural frequency and sensitiveness, shows other oscillations which are of lesser amplitude but which occur at definite moments of the cycle, *e.g.*, vibrations due to the second heart sound.

The *a* wave coincides with, and is due to, auricular systole. It begins at the same time as auricular contraction, but the end of auricular systole is not always clearly marked in the phlebogram. The descending limb of *a* begins when the first muscular units of the auricle relax, and continues to fall until all the fibers are relaxed. The end of this descending limb coincides with the intersystolic period (when there is one) and passes without transition to the oscillations which occur during isometric contraction of the ventricles. These oscillations are not very typical nor prominent.
Fig. 120. "Arterialized" venous pulse. Phlebogram, phonocardiogram obtained by direct optical registration, and ECG; simultaneous records from a normal man. The *c* wave is prominent and similar to the central arterial pulse. (*Caeiro, 1942.*)

The *a* wave is absent in the phlebogram of cases of auricular fibrillation (Fig. 121). In auricular flutter the phlebogram consists of a series of *a* waves, interspersed periodically by the *c* and *v* waves of ventricular activity (Fig. 75).

The origin of the *c* wave has been the object of much discussion. Optical records undoubtedly

[1] Caeiro, A., *Medicina, Buenos Aires*, 2, 257, 1942.

show this wave to be due to an increase in venous pressure occurring during the ejection phase. At the same time intra-auricular pressure falls because of three concurrent circumstances: (*a*) the auricular muscle relaxes; (*b*) the A-V septum descends rapidly, because of ventricular contraction, which exerts a "sucking" effect on the auricle; (*c*) intrathoracic pressure falls, because the blood ejected by the ventricle sends blood out of the thorax, and this fall in pressure is transmitted to the auricles through its flaccid walls.

The intra-auricular pressure curve, therefore, shows no wave corresponding to the *c* wave of the phlebogram; consequently the latter must be of extracardiac origin. Mackenzie[1] thought this wave was due to an impact of the carotid artery and for this reason called it the *c* (carotid) wave. Wiggers[2] made careful comparative studies of the pressures in the right auricle, the veins, and the aorta, with the venous pulse, in simultaneous records with optical-registration methods of adequate efficiency. He concluded that the *c* wave is due to an arterial impact, but not necessarily to that of the carotid, because it persists after the carotid has been extirpated.

The carotid pulse, nevertheless, is partially registered in an ordinary phlebogram, and the *c* wave frequently shows the characteristics of the carotid pulse wave optically recorded. The *c* wave is less prominent as the record becomes a more exclusively venous pulse; if this wave is scarcely noticeable, the phlebogram can be called a pure venous pulse. In arterialized venous pulse records, the *c* wave shows some of the features of the central arterial pulse, and in mixed venous pulse records the appearance of *c* is intermediate between the two former cases (Figs. 119 and 120).

The depression *x*, following the *c* wave, is due to the fall in auricular pressure during the ejection phase of ventricular systole. It is more marked when the arterial impact is small, because the latter tends to suppress it. On the contrary, strongly arterialized phlebograms show almost no *x* depression.

The *v* wave usually begins at the end of the ejection phase.

If there is a very prominent *c* wave, the *v* wave begins in the diastole. The ascending limb of *v* is due to the progressive accumulation of blood in the auricle and veins while the A-V valves remain closed. The top (usually acute) marks, and is due to, the opening of the A-V valves. The veins are emptied by the flow of blood into the ventricles. The descending limb of *v* corresponds, therefore, to the rapid filling of the ventricle.
FIG. 121. Venous pulse in auricular fibrillation. Phlebogram, phonocardiogram, and ECG in a case of auricular fibrillation. The *a* wave of the phlebogram and the P wave in the ECG are missing. (*Orías, O., and E. Braun Menéndez, 1937.*)

On the ascending limb of the *v* wave in optical records there is always a notch, which corresponds to the second heart sound. If the segment capsule is very sensitive there will be two or three oscillations instead of a notch. This record of the second heart sound is very useful because it marks fairly precisely the end of the ejection phase and the beginning of isometric relaxation, which ends at the apex of the *v* wave.

The depression *y* is formed by the descending limb of *v* and the following rise in the record. This rise is due to the accumulation of blood in

[1] MACKENZIE, J., *J. Path. & Bact.*, 1, 53, 1893.
[2] WIGGERS, C. J., "The Pressure Pulses in the Cardiovascular System," Longmans, New York, 1928.

the auricle and veins after the ventricle has been filled and to the gradual increase in volume of the veins up to the beginning of the next cycle. If the diastolic pause is lengthened, a fourth wave, *h*, is observed. This wave occurs when there is no cardiac activity, and if the diastole is even more prolonged, other similar waves are seen. All these are of low frequency and of decreasing amplitude. At this moment of the cardiac cycle, ventricle, auricle, and veins form one large venous reservoir. The *h* and similar waves have been interpreted as vibrations of this reservoir caused by the reflection of the wave due to the rapid inflow into the ventricles on the opening of the A-V valves (Caeiro).

The *x* depression is frequently called the systolic collapse of the venous pulse, and the *y* depression the diastolic collapse.

Velocity of transmission of the venous pulse. The waves of the venous pulse are transmitted at much lower speed than the waves of the arterial pulse. Moreover there are great differences in the velocity of transmission of the different waves. These are due to differences in the mechanism of production, in the degree of filling of the veins, and in the velocity of the blood at the moment each wave appears.

In the dog, according to Caeiro,[1] the beginning of *v* spreads very slowly (0.85 m. per sec.) and the apex is transmitted at much higher velocity (3.86 m. per sec.). The *a* and *c* waves spread at velocities of 1.40 and 1.70 m. per sec. respectively. The oscillations of the second heart sound spread with a velocity of 4.70 m. per sec.

The heart cycle as portrayed in the phlebogram. The following phases of the cardiac cycle can be delimited fairly precisely in the phlebogram: auricular systole, or presystole (*a* wave); ventricular ejection phase (from the beginning of *c* to the oscillations of the second heart sound); isometric relaxation (from the second heart sound to the top of *v*); rapid filling of the ventricle (from the top of *v*, caused by opening the A-V valves, to the bottom of *y*); and diastasis (from the bottom of *y* to the beginning of *a* in the next cycle) (Fig. 114).

The A-V conduction time is marked in the phlebogram by the interval between the beginnings of *a* and *c*; normally it is not more than 0.20 sec. The *a-c* interval in the phlebogram is the equivalent of the PR interval in the electrocardiogram and, before Einthoven's work with the string galvanometer, was the only means of measuring A-V conduction time.

[1] Caeiro, A., *Rev. argent. de cardiol.*, **8**, 329, 1941.

The phlebogram is the record that permits the recognition of the greatest number of phases in the cardiac cycle. It affords the simplest and surest method of measuring the duration of the diastolic phases. Finally, as a reference tracing it is of great value for the precise localization in the cardiac cycle of acoustic and other signs of cardiac activity.

Some observers have tried to assess the dynamic conditions of cardiac activity and the distensibility of the heart walls by a minute analysis of the waves of the phlebogram, especially of their amplitude. The legitimacy of these conclusions is questionable, since in the same subject the records vary considerably according to the pressure exerted on the exploring funnel or its position with regard to the vein, without any reference to the conditions of cardiac activity.

CHAPTER 24

Special Vascular Circuits

THE CIRCULATION THROUGH certain parts of the organism, because of morphologic and functional characteristics, deserves special consideration. One such circuit, the coronary system of the heart, has already been dealt with (see Chap. 18). Others will now be studied.

PULMONARY CIRCULATION

The pulmonary circuit consists of the pulmonary arteries, capillaries, and veins. The blood returned by the systemic veins to the right auricle is ejected into this circuit by the right ventricle. As it passes through the pulmonary capillaries the blood comes into close contact with the alveolar air, and the process of hematosis takes place, *i.e.*, CO_2 is lost and oxygen is taken up by the blood. The arterialized blood is then carried to the left auricle by the pulmonary veins. In the pulmonary circuit the arteries have thinner and less elastic walls than in the aortic circuit; they are also shorter and branch out more profusely. The peripheral resistance is much less than in the general circulation.

Pulmonary capillaries form a kind of hood closely fitted on the alveolar walls. Microscopic observation by transillumination shows the blood flowing through them continuously without pulsation, the erythrocytes passing in single file within the narrow capillaries.

Between the pulmonary and bronchial circuits (the latter branching off from the aortic system) there are only capillary anastomoses, without functional significance in normal conditions.

The pulmonary circuit has been explored directly in animals and man by introducing a catheter through the right ventricle[1] or by transthoracic puncture of the pulmonary artery.[1] Records of the blood pressure at different levels of the pulmonary artery can thus be obtained by connecting the catheter with an adequate manometer. In the main branches of the pulmonary artery the records show a similar contour to that of pressure records of the aorta, but at lower levels (Fig. 122). If the catheter is introduced until it can no longer advance (because it fills, and therefore occludes, the lumen of the vessel), a record is obtained, called the *capillary pulmonary pressure*,[2] which registers by retrograde transmission the pressure in the obstructed territory distal to the end of the catheter

In healthy subjects lying on their backs, the

[2] HELLEMS, H. K., F. W. HAYNES, and L. DEXTER, *J. Applied Physiol.*, **2**, 24, 1949.

pulmonary circulation has the following characteristics:[1] minute volume, 5.5 liters/min., *i.e.*, 3.1 liters/min. per sq. m. of body surface; systolic pressure in the main branches of the pulmonary artery, 22 ± 2.9 mm. Hg; diastolic, 8 ± 1.7; mean, 13 ± 2.3; capillary pulmonary pressure, 5 mm. Hg.

The average oncotic pressure of plasma proteins is 25 mm. Hg; therefore water cannot filter through the capillary endothelium into the alveoli, and normally the alveolar cavity is free from fluid.[2] If pulmonary capillary pressure increases to a figure above the oncotic pressure of plasma proteins (*e.g.*, in left ventricular insufficiency) or if the capillary endothelium is damaged (*e.g.*, by toxic gases), fluid passes out of the capillaries and floods the alveoli, which become useless for hematosis (pulmonary edema).

The resistance of the pulmonary circuit is so low that in dogs[3] it is possible to destroy 90 per cent of the muscle of the right ventricle without causing changes in the pulmonary, aortic, or venous pressure. Apparently tension arising passively in the inactivated right ventricle owing to the contraction of the left ventricle is sufficient to convert the right ventricle into an efficient pump capable of maintaining a normal pulmonary circulation.

Recent work on the much-discussed question of the regulation of the diameter of pulmonary vessels by vasomotor nerves seems to prove that this type of regulation does not exist.[4]

The pulmonary circuit can act as a blood reservoir and take part in the regulation of the circulating blood volume.

Drinker and his collaborators[5] have demonstrated that storage of blood in the lung takes place at the expense of the air space. Changes in vital capacity observed, according to whether a subject is standing up, sitting, or lying down, are due to variations in the amount of blood stored in the lung in the different positions.

[5] Drinker, C. K., F. W. Peabody, and H. C. Blumgart, *J. Exper. Med.*, **35**, 77, 1922.

Redistribution of blood after partial pulmonary collapse, pathologic pulmonary processes, or surgical removal of part of the lung depends on local mechanical conditions. When there is a local increase in peripheral resistance limited to one lobe or part of a lobe, blood is shunted toward the intact parts of the lung. The large capacity of the pulmonary vascular bed facilitates redistribution. Thus in patients with only one lung, in which twice the normal amount of blood circulates, right ventricular pressure does not increase (Cournand).

CEREBRAL CIRCULATION

The nutrition of the brain is assured by the internal carotid and vertebral arteries, which anastomose to form the circle of Willis. This circle gives out arterial trunks which ramify and form the arterial network of the pia. From this network terminal arterioles penetrate into the depth of the brain. Occlusion of one of these arteries causes necrosis of the tissues it serves; "softening" thus produced disturbs the functions of the damaged centers and tracts.

The blood circulates in the brain through an incompressible mass enclosed in a cavity with inextensible walls (the cranium); therefore any amount of blood coming in by the arteries must cause the evacuation of an equivalent amount through the veins. This fact was pointed out by Monro in 1783 and is now known as the Monro-Kellie principle. Consequently, circulatory changes in the brain are brought about more by modification of the velocity of flow than by changes in the diameter of the blood vessels.

The cerebral blood vessels are nevertheless provided with vasomotor nerves. Stimulation of the cervical sympathetic produces all the signs of vasoconstriction in the encephalic mass of the corresponding side. Stimulation of the vagus, on the contrary, provokes vasodilatation.

Histamine dilates the vessels of the pia and increases their pulsation, causing headache. Local application of adrenaline provokes vasoconstriction, but injection of a dose sufficient to produce general effects causes the blood vessels of the brain to dilate passively, because the rise in blood pressure produced by vasoconstriction (especially in the splanchnic area and the skin) sends more blood into them. Ether and CO_2 act locally on the cerebral vessels and cause them to dilate.

The cerebral minute volume can be determined by the method proposed by Kety and Schmidt.[1] The subject breathes nitrous oxide so as to accumulate this gas in the blood at a concentration below the anesthetic level, and the Fick principle is applied in order to establish the amount of gas taken up by the tissues. The concentration of nitrous oxide in (*a*) arterial blood, (*b*) cerebral venous blood, and (*c*) cerebral tissue, is determined in samples drawn from the radial or femoral artery and the bulb of the internal jugular vein. The concentration in cerebral tissue is deduced from the concentration in venous blood when an equilibrium is established between the concentration of nitrous oxide in blood and in the tissues (it takes 10 min. to establish this equilibrium). With these data it is possible to calculate the cerebral minute volume. To determine the oxygen or glucose consumption of the brain, the arteriovenous difference in oxygen or glucose concentration is multiplied by the minute volume. Cerebral vascular resistance is equal to the ratio between the mean arterial pressure and the cerebral minute volume.

Normal subjects[2] have an average cerebral minute volume of 65 ml. of blood per min. per 100 gm. brain tissue, *i.e.*, approximately 14 per cent of the total cardiac output. The oxygen and glucose consumption are 3.8 ml. of oxygen and 6.2 mg. of glucose per min. per 100 gm. of brain tissue.

HEPATIC CIRCULATION. PORTAL SYSTEM

The circulation through the liver is peculiar in many respects. After birth the liver receives blood from two sources, the portal vein and the hepatic artery. The portal vein carries 75 per cent of the blood coming to the liver, but the 25 per cent brought by the hepatic artery is indispensable; if it is suppressed by tying this artery, the liver degenerates rapidly and the subject dies.

Treatment with large doses of penicillin prevents, in a high proportion of the cases, the hepatic necrosis thus provoked.[3] This finding suggests that necrosis is due to proliferation of anaerobic germs, which penicillin inhibits. The main role of the hepatic artery would therefore be to maintain a sufficiently high oxygen pressure to prevent growth of anaerobic bacteria, which are usually found in the phagocytic Kupffer cells after they have been absorbed from the intestine.

[1] Kety, S. S., and C. F. Schmidt, *Am. J. Physiol.*, **143**, 53, 1945; *J. Clin. Investigation*, **27**, 476, 1948.

These findings have led to the treatment of hepatic cirrhosis by ligation of the hepatic artery. The procedure has been used successrully in emergency treatment of hemorrhage due to rupture of varicose veins in the esophagus caused by hepatic cirrhosis.[1]

After entering the liver the portal vein branches out profusely. The final divisions run in the interlobular spaces and form around the lobules the periportal capillary network, of which the capillaries of the hepatic artery are also part. The sinusoids arise in the periportal capillary network and radiate into the lobules between the hepatic-cell columns toward the central vein which opens into a sublobular branch of the suprahepatic vein, tributary of the inferior vena cava. The muscle layer of the suprahepatic veins thickens considerably at the level of its opening into the inferior vena cava, thus forming a sphincter which regulates the flow of hepatic blood into the inferior vena cava. In the dog, however, hepatic congestion seen in shock (anaphylactic, histamine, etc.) is due to a diffuse spasm of the entire hepatic venous side of the liver, rather than to constriction of a more or less circumscribed sphincter.[2]

Microcinematographic studies *in vivo* of the amphibian liver have shown that the circulation in the intralobular sinusoids is fairly complicated. Blood flow and pressure are controlled by microscopic sphincters placed along the course of the sinusoids and in their opening into the central vein.[3]

The pressure in the portal vein has been measured in experimental animals; it is from 8 to 12 mm. Hg. In the hepatic artery it is 120 to 130 mm. Hg.

The hepatic minute volume in man can be calculated by the following method: Urea concentration in hepatic blood is determined by collecting a sample

[1] Chenoweth, A. I., *Ann. Surg.*, **135**, 756, 1952.

[2] There is suggestive but so far inconclusive evidence that a similar mechanism may be present in other animals (cat, white rat) and in man (Thomas, W. D., and H. W. Essex, *Am. J. Physiol.*, **158**, 304, 1949).

[3] Knisely, M. H., E. H. Bloch, and L. Warner, *Kgl. Danske Vidensab. Selskab., Biol. Skr.*, **4**, No. 7, 1948.

by means of a catheter introduced into an arm vein, then through the superior vena cava and right auricle into the inferior vena cava. Urea concentration in arterial blood and the amount of urea excreted by the kidney in given time are also determined. The minute volume of blood flow through the liver is then calculated by applying Fick's principle.[1] The elimination of bromsulfonphthalein injected has also been used for this purpose, applying a similar procedure.

In 73 normal men the hepatic minute volume was found to be 1,580 ± 32.5 cc./sq. m., and 1,340 ± 46.6 cc./sq. m. in 18 normal women. Patients suffering from hepatic cirrhosis had significantly smaller hepatic minute volumes.[2] When the subject stands up the hepatic minute volume decreases 40 per cent.[3]

The distribution of the portal system is such that all the blood from the abdominal viscera, especially from the intestinal tract, must come into close contact with the hepatic cells, which considerably modify this blood. Some substances brought by the portal blood are changed and stored in the liver cells; others are manufactured by the liver and confer to the blood some of its essential properties, *e.g.*, fibrinogen and prothrombin. The large and variable capacity of the portal system makes it an important blood reservoir, which plays a major part in the regulation of the circulating blood volume.

Sudden occlusion of the portal vein causes hemodynamic disturbances which rapidly end in death. Blood accumulates in its tributaries and the rest of the organism suffers from anemia. The animal, it has been said, bleeds itself into its own abdominal viscera.

Gradual occlusion of the portal vein is observed in cases of cirrhosis of the liver. In this disease proliferation of fibrous connective tissue strangles the blood vessels in the liver, and the portal blood finds its way to the vena cava through anastomoses that are normally minute and not visible. These anastomoses develop gradually into large vessels and form a conspicuous venous collateral circulation, draining the blood from the abdominal viscera into the vena cava.

The double blood supply of the liver (portal vein and hepatic artery) and the behavior of the heart in hypoxia, which differs according to whether the liver is excluded or not from the circulation, have led Rein[1] to postulate two types of hepatic function: (*a*) the ingestive function, in which the portal system plays the main part, the object of this function being to take up and process nutritive substances; and (*b*) the regulation of oxidation, in which the hepatic artery plays the main part. According to Rein, the liver contributes to the relief of general or local oxygen deficiency. The heart, the organ most studied in this respect, in conditions of hypoxia is assisted by a substance (*hypoxie-lienin*) released from the spleen by a nervous mechanism when there is an insufficient oxygen supply. This substance, on passing through the liver, acquires properties similar to those of strophanthin and regulates oxidative mechanisms in the myocardium. Activation of *hypoxie-lienin* in the liver requires the blood supplied by the hepatic artery.

Extirpation of the liver has been performed experimentally and has given important information on hepatic functions. Special measures must be taken to prevent death from circulatory disturbances caused by the ligature of the portal vein and the inferior vena cava; otherwise the animal dies before functional changes due to the absence of the liver become evident. Mann and Magath[2] were the first to obtain satisfactory results. The operation is performed in three stages, separated by intervals of several days:

1. Surgical anastomosis of the inferior vena cava into the portal vein (an inverted Eck fistula; see below), in order to increase the flow and pressure in the portal system so that a collateral circulation will develop, draining the system into the superior and inferior venae cavae above the level of the liver.
2. Ligature of the portal vein immediately before its entrance into the liver, an operation which is now well tolerated, because of the collateral circulation already developed.
3. Removal of the liver, which is considerably atrophied as a consequence of the second operation.

Hepatectomy can be performed in a single operation if the portal vein is anastomosed to the inferior vena cava and the segments of the vena cava above

and below the hepatic veins are joined by a Pyrex glass tube.[1]

Eck's fistula is an anastomosis of the portal vein into the inferior vena cava, with the aim of excluding the liver from the portal circulation. The results are incomplete and transitory.

SPLENIC CIRCULATION

The spleen plays a part in the regulation of the circulation, especially in certain circumstances. The stroma and venous sinuses of the spleen give it the aspect of a sponge soaked in blood. The activity of the smooth-muscle fibers of the spleen causes its blood content to vary. The spleen is a blood reservoir which can remove from the circulation, or eject into it, appreciable quantities of blood, according to the state of relaxation or contraction of its muscles. Adrenaline and sympathetic stimulation contract the muscles of the spleen and therefore cause it to eject blood into the circulation. During exercise, asphyxia, cold, etc., the spleen volume becomes smaller.

Blood passes through the spleen in vessels with continuous although very thin walls. These capillaries allow the passage into the extravascular spaces of the red pulp not only of plasma but also of small particles and even erythrocytes.[2]

Blood stored in the spleen undergoes a process of concentration; the proportion of erythrocytes to plasma increases. This concentration is such that when the spleen contracts and ejects blood into the circulation, the erythrocyte count increases. Thus the spleen takes part not only in the control of the circulating blood volume, but also in the regulation of the number and concentration of erythrocytes.

CIRCULATION TIME[1]

The time taken by the blood to traverse a part or the whole of a vascular circuit is called the circulation time. It can be measured by several methods, some of which can be applied in man. In general, a substance is injected into a peripheral vein and the time it takes to arrive at another point of the vascular system is measured.

Table 19. Circulation Time in Healthy Persons

	Substance used	*Circuit*	*Indicator*	*Circulation time, sec.*
Fischberg *et al.*	Saccharine	Arm–tongue	Sweet taste	9–16
Robb and Weiss	Sodium cyanide	Arm–respiratory center	Respiratory stimulation	9–21
Hitzig	Ether	Arm–lung	Smell	3.5–8
Spier *et al.*	$MgSO_4$ and Ca gluconate	Arm–throat	Heat	7–22
Stanojevic	Lobeline	Arm–coughing center	Cough	10.6 (av.)
Bernstein and Simkins	$MgSO_4$	Arm–throat	Heat	7–17.8

Many substances have been used: dyes, electrolytes, substances with a peculiar taste or odor, functional stimulants (vasodilators, stimulants for the carotid sinus or the respiratory center, etc.), radioactive isotopes, etc. In the histamine method[2] an adequate dose is injected into a vein in the arm and the time taken for the face and neck to flush is measured. At the same time the subject perceives a metallic taste, which can also be taken as the end point of the test. Histamine provokes headache, and this fact has limited its use. Other substances have been proposed: fluorescein (dye); sodium dehydrocholate, known as decholin, which gives a bitter taste; CO_2, which is inhaled and stimulates the respiratory center (this method measures the circulation time of the lung–respiratory center circuit); sodium cyanide (respiratory stimulant); lobeline (stimulates coughing); saccharine (sweet taste); sodium sulfate (sensation of heat in pharynx); calcium gluconate (sensation of heat in mouth and bitter taste); ether (sensation of smell).

Heart J.*, **10**, 1080, 1935; Spier, L. C., I. S. Wright, and L. Saylor, *Am. Heart J.*, **12**, 511, 1936; Stanojevic, L., *Ztschr. f. Kreislauff.*, **30**, 521, 1938; Bernstein, M., and J. Simkins, *Am. Heart J.*, **17**, 218, 1939; Wall, H. C., *Am. Heart J.*, **18**, 228, 1939; Walz, L., and G. Zimmermann, *Ztschr. f. Kreislauff.*, **40**, 2, 1951.
[2] Weiss, S., G. P. Robb, and H. L. Blumgart, *Am. Heart J.*, **4**, 1, 1929.

Circulation times observed with different methods are given in Table 19.

Considerable variations are found even in normal subjects, because the circulation time is conditioned by many factors: functional condition of the myocardium, minute volume, basal metabolism, blood distribution in the body, tone of vascular muscles, blood volume, composition and viscosity of the blood, hemoglobin concentration, number of erythrocytes, etc. The circulation time is considerably increased whenever there is any circulatory impediment. In cases of decompensated heart failure, the circulation time may be increased up to three times the normal.

Table 20 summarizes Vierordt's experiments in several species on the time taken for the blood to make a complete circuit from jugular vein to jugular vein. In these experiments the blood must pass through the aortic and pulmonary circuits. As the table shows, the number of heartbeats needed for a complete circuit is almost the same in all species. A longer circulation time is found in longer circuits (*e.g.*, femoral vein to femoral vein). The difference, nevertheless, is not considerable because the

Table 20. Time of Complete Circuit Related to Heart Rate

Animal	*Complete circuit time, sec.*	*Heart rate, beats per min.*	*Number of beats for complete circuit*
Rabbit	7.46	210	26.1
Sheep	14.14	110	26.0
Dog	16.7	96	26.7

* Figures calculated supposing man's size as intermediate between those of the dog and the horse.

greater part of the circulation time is taken up in crossing the capillary network; the blood circulates in arteries and veins at such a speed that differences in length are not of much importance.

CHAPTER 25

The Lymphatic System. The Cerebrospinal Fluid

THE LYMPHATIC SYSTEM

The lymphatic system is morphologically and functionally accessory to the blood vascular system. Its principal function is to carry back to the blood those products of cellular metabolism, or foreign substances, which cannot be reabsorbed into the blood capillaries. Some of the functions of the lymphatic system, such as the part it plays in immunity and in intestinal absorption, have taken on peculiar features, but these are only a special development of its general function of scavenging and draining the tissue spaces. The lymphocytes and monocytes of the blood are formed in the lymph nodes.

Gaspar Aselli, professor of anatomy in the University of Pavia, is credited with the discovery of the lymphatics. In 1622 he enthusiastically drew the attention of his contemporaries to these vessels, which are easily seen in the mesentery of a dog in the course of digestion, when they are filled with a milky fluid. Influenced by Galen's theories, he thought the lymphatics carried substances to the liver for the formation of the blood. A few years later (1651) Pecquet, a French physician, described the receptaculum chyli, also known as the cistern of Pecquet, and the thoracic duct with its opening into the veins in the neck. Later Rudbeck and Thomas Bartholin, who was the first to call these vessels the lymphatics, found them in other organs and tissues. By 1700 the existence of a vast system of vessels, different from the blood vessels, draining all parts of the body into the veins, was well known.

Anatomical distribution. The lymphatic capillaries have their origin in the intercellular spaces. They have endothelial walls, which are sometimes extremely thin and can be seen only with great difficulty, but which are never missing. There is general agreement that lymphatic vessels form, at their origin, a closed system; their content is not in direct contact with the cells, nor does it mix with the tissue fluids (Fig. 123).

At their site of origin lymphatic vessels have numerous anastomoses with each other and form a vast network containing the tissue cells in its meshes. From the capillary network collecting trunks arise; they are of larger diameter, have thicker walls, and are provided with valves that prevent the lymph from flowing back to the tissues. These trunks flow into others of still larger diameter, and in the higher mammals they end in two principal vessels: (*a*) the thoracic duct, which collects the lymph from all the parts below the diaphragm, including the abdominal viscera, and from the left half of the body above the diaphragm; (*b*) the right lymphatic duct or lymphatic vein, which collects the lymph from the right side of the body above the diaphragm.

The thoracic duct is the most important of all the lymphatic vessels. It joins the venous system at the angle formed by the junction of the left subclavian and jugular veins. The right lymphatic duct ends in the corresponding venous junction, on the right side.

The lymphatic trunks are of much smaller diameter than the arterial and venous trunks. Their walls are much thinner and are made up of endothelium surrounded by collagenous fibers and a few muscle fibers. The thickness of the walls and of the muscular coat increases with the diameter of the vessels.

In their course the lymphatics pass through structures, known as lymph nodes, made up of a connective-tissue stroma which sustains a large number of lymphocytes, reticular cells, and fixed macrophages; the whole is surrounded by a connective-tissue capsule. The afferent lymphatics of the nodes flow into sinuous

clefts called lymphatic sinuses, and these in turn empty into the efferent lymphatics. Lymph flowing through a node literally filters through it. Lymphocytes and monocytes are formed in the lymph nodes. These cells eventually pass into the blood together with the lymph.

Fig. 123. Lymphatics of the myocardium. A large collecting vessel and small capillary network. Note the irregularity of the vessel walls and the numerous anastomoses. (*After Bock, H., Anat. Anz., vol. 27, p. 40, 1905.*)

Methods of study. There are two principal methods for studying the lymphatic system: (*a*) a cannula is introduced into a lymphatic trunk and the lymph is collected, observing its rate of flow, amount, chemical composition, etc.; (*b*) the tissues are cut and a dye is placed in the wound, so that the coloring matter penetrates into the lymphatics and renders them visible. Drinker and his collaborators, and others before them, have obtained valuable information using the former of these methods; MacMaster and his collaborators have used the latter.

The formation of lymph. Lymph is formed by filtration of tissue fluids into the lymphatic capillaries. Ludwig was the first to postulate the existence of this mechanism of lymph formation; his ideas were given further experimental support by Starling, and they have found ample confirmation in more recent work. Lymphatic capillary endothelium plays a passive part in this process. It is not yet known how colloid and larger particles pass into the lymphatics. Foreign substances which have found their way into the tissues have a tendency to enter the lymphatics, unless they consist of very large particles.

In normal conditions lymph is formed from the excess of tissue fluid filtered and not reabsorbed by the blood capillaries (Fig. 117). Lymph formation is almost continuous in the intestinal tract, liver, and heart. In other tissues, lymph is formed in appreciable quantities only at certain times, as when filtration from the blood capillaries increases because the cells become active, or the tissues are massaged, or warmed, etc. The mechanism of filtration through the blood-capillary endothelium has been discussed in Chap. 22.

The amount of lymph formed varies considerably in different parts of the body at different times. Crandall *et al.*[1] were able to collect all the lymph flowing from the thoracic duct in a patient with a lymphatic fistula in the neck. The flow in basal conditions amounted to 1.38 cc per hr. per kg. of body weight. Maximum flow was observed after a meal; it was then 4 cc per min. per kg. Abdominal massage, or ingestion of water, oil, or protein, increased the flow by 3.19 to 5.28 per cent above the basal level.

Lymphagogues are substances that provoke an increase in lymph formation. Heidenhain made a detailed study of these substances and divided

[1] *Gastroenterology*, 1, 1040, 1943.

them into two classes. Lymphagogues of the first class are relatively complex and of many different kinds; they are found in tissue extracts, commercial peptone, etc. Lymphagogues of the second class are relatively simple crystalloids such as salts, urea, glucose, etc.

All the lymphagogues increase lymph production by modifying the process of filtration through the blood capillaries. Lymphagogues of the first class probably damage the capillary endothelium; they act on all the capillaries, but with particular intensity on the liver capillaries. Their action on the skin capillaries causes extensive cutaneous eruptions, with formation of wheals. Histamine, which is found in most of these extracts, produces the same effect.

Copious injections of aqueous solutions of crystalloids dilute the blood and diminish the oncotic pressure of the plasma proteins. This causes an increase in filtration of fluid from the capillaries to the tissues and in the formation of lymph.

Lymphagogues of the first class provoke the formation of concentrated lymph with a high protein content. Lymphagogues of the second class form dilute lymph with little protein.

Chemical composition and properties of lymph. The chemical composition of lymph varies considerably from one lymphatic territory to another. Even lymph from the thoracic duct, which comes from many and diverse territories, varies in composition according to the physiologic circumstances. With the exception of lymph coming from the intestine, which contains fats and other substances absorbed from the digestive tract, lymph is a watery solution of the same substances as are found in blood plasma. Crystalloid electrolytes in lymph are the same as those of blood plasma and are found in almost the same concentration. The protein concentration, on the other hand, is lower and variable. Lymph flowing from the thoracic duct has 3.2 per cent protein. Lymph from the limbs has 2.3 per cent protein, but this can fall to 0.5 per cent or less in the course of vigorous exercise. If the pressure in the hepatic veins is increased by partial occlusion of the inferior vena cava, the protein concentration of the lymph in the thoracic duct rises almost to the level of that in the blood plasma.[1]

The proteins in the lymph are the same as those in blood plasma, and it is thought that they escape from the blood through the blood-capillary endothelium. This escape is probably due to the frequent disturbance in capillary permeability caused by ischemia and other factors that act occasionally on the endothelium. These proteins pass from the tissue fluids into the lymphatics and are thus returned to the blood.

Fibrinogen also passes into the lymph. It is responsible for the coagulation of the lymph in the same way as for blood coagulation.

Thoracic-duct lymph has a milky appearance because of its high fat content, which increases during intestinal absorption, especially if the meal is rich in fats. Approximately 60 per cent of the total fat absorbed goes to the blood through the lymphatics. This is due probably to the formation of fat droplets in the process of absorption by the intestinal epithelium.

Lymphocytes are almost the only cells found in lymph. Occasionally monocytes are seen, and even less frequently granulocytes, usually eosinophils. In certain circumstances erythrocytes are found in the lymph. Lymphocytes are the specific lymphatic cells, formed in the lymph nodes and other lymphatic structures; other cells enter the lymph accidentally. The number of lymphocytes in the lymph varies considerably according to the territory and the circumstances in which the lymph is collected. In man between 2,000 and 20,000 per cu. mm. have been found.

The specific gravity of the lymph is 1.016 to 1.023. Osmotic pressure and alkaline reserve are slightly greater than in blood plasma; the viscosity is slightly less.

The lymph flow. Lymph flows from the tissues, where it is formed, to the opening of the collecting trunks in the veins of the neck. Several factors are responsible for its motion, which is similar to the blood flow in the veins. Valves direct and assist the progress of the lymph, but frequently valvular insufficiency permits its reflux.

Certain species (amphibians, reptiles, a few birds such as the swan, stork, goose, and ostrich) have lymph hearts, which drive the lymph forward. In amphibians there are two anterior and two posterior lymph hearts, one at the root of each limb. They have striated muscles and are innervated by fibers coming directly from the spinal cord. If these fibers are cut or the spinal cord is destroyed, the lymph hearts

[1] Starling, E. H., "The Fluids of the Body," Constable, London, 1909.

cease to beat. Under normal conditions the lymph from the limb and neighboring lymphatic sacs flows into the corresponding lymphatic heart and, because of the activity of the latter, is propelled into a short efferent lymphatic trunk which ends in the nearest large vein. Valves in this trunk direct the flow of lymph toward the vein. Destruction or paralysis of the lymph hearts causes death in a few days. Body weight increases considerably, and the blood becomes greatly concentrated because of the accumulation of fluid in the tissues.[1] The circulation of the lymph and its return to the blood are essential for life and the activity of the lymph hearts, in the animals under consideration, is indispensable for this circulation. Capillary filtration in these animals, in normal conditions, is considerably greater than in mammals. Obstruction of the lymph circulation causes "plasmatic hemorrhage" into the lymphatic sacs, a condition similar to mammalian shock.

In mammals there are no special organs that propel the lymph. Lymphatic trunks have plain-muscle fibers, and even in the small peripheral lymph vessels there are slow, rhythmical, active movements, peristaltic in some parts. Heller[2] counted about 10 pulsations per minute. The valves assure the progress toward the veins of lymph displaced by the contraction of the lymphatic musculature. Thus every segment between two valves acts as a miniature heart.

Muscles in the lymphatics respond to electrical stimulation and are under nervous control. The mechanism of the nervous regulation of lymphatic circulation in mammals is still unknown.

Apart from the activity of the muscles in the lymphatic walls, other forces contribute efficiently to the circulation of the lymph. "Negative" intrathoracic pressure, due to the elastic recoil of the lung, exerts a permanent aspiratory effect on the lymphatic system in the same way as on the venous system. This effect increases at each inspiration. The movements of the diaphragm act by a double mechanism on the lymphatic circulation: (*a*) the diaphragm is an inspiratory muscle and therefore its contraction increases the negative thoracic pressure; (*b*) on contracting, the diaphragm increases abdominal pressure, and by direct or indirect compression

[1] Braun Menéndez, E., and V. G. Foglia, *Arch. internat. de pharmacodyn. et de thérap.*, 64, 273, 1940.

[2] Heller, A., *Centralbl. f. d. med. Wissensch.*, p. 545, 1869.

of the lymphatics, especially of Pecquet's cistern, it propels the lymph toward the thorax.

Contraction of skeletal muscles has the same effect on lymphatic as on venous circulation, because of the flaccidity of the lymphatic walls and the existence of valves. The lymphatic vessels are squeezed between the muscles and emptied toward the veins. Fluctuations in pressure caused by the pulsation of neighboring arteries have the same effect. MacMaster[1] observed that perfusion of a rabbit's ear through its artery with a pulsating stream caused the lymph to flow at a speed 15 to 20 times that observed when the same ear was perfused at a constant pressure kept at the maximum level of the pulsating pressure.

Gravity helps or hinders the circulation of lymph according to whether the lymphatic territory is placed above or below its opening into the veins.

Velocity of flow and pressure in the lymphatics. The flow of lymph is neither continuous nor of uniform velocity; at times it has a pendulum movement.

If sodium sulfindigotate (indigo carmine) is injected into the leg of a dog, the dye is seen in the thoracic duct 10 min. later.

A warm temperature, activity, and hyperemia increase the velocity of flow; rest diminishes it.

Pressure within the lymphatics diminishes progressively from the tissues to their opening in the veins. Few accurate determinations of lymphatic pressure have been reported. In the ear of a mouse kept perfectly still, direct measurements made with micromethods have shown the pressure to be 0.7 ± 0.3 cm. H_2O.[2] In the thoracic duct, near its opening into the veins of the neck, the pressure is a few centimeters below atmospheric pressure. This difference in pressure causes the lymph to flow from the tissues to the veins.

In cases of heart failure with edema, MacMaster has observed that lymph remains almost stationary in the lymphatics of the skin. In cases of nephrosis with edema, on the other hand, lymph flows at a higher velocity than in normal conditions.

Lymphatic occlusion. Elephantiasis. Complete occlusion of the thoracic duct causes the accumulation of a milky fluid in the pleural and peritoneal

[1] MacMaster, P. D., *Harvey Lect.*, 37, 227, 1942.

[2] *Ibid.*

cavities (chylous ascitis). In the superficial territories there are no prominent changes, because they are drained through the numerous anastomoses of the lymphatic network. Complete obstruction of the thoracic duct may be observed in cases of mediastinal tumor.

In the limbs, lymphatic occlusion produces abnormal signs only when nearly all the lymphatic trunks have been obstructed. In such cases, considerable and progressive edema is produced. At first it is soft and depressible, but later it increases in consistency and becomes hard because of the proliferation of fibrous tissue. The diseased limb can take on gigantic proportions. When the condition has progressed to this stage it is called "elephantiasis," because the limbs look like those of an elephant. Infestation by parasitic worm (*Filaria*) is a frequent cause of this disease in some Oriental countries. It can be reproduced in experimental animals by obstructing the lymphatics with silica or other inert powders (Drinker).

Drinker suggests that pneumoconiosis is a kind of pulmonary elephantiasis, in which inhaled particles of dust penetrate the lymphatics of the lung and are carried to the regional lymph nodes. If there is an excessive accumulation of these particles, lymphatic obstruction is inevitable.

The lymphatic system and immunity. The lymphatic system plays an important part in the processes of immunity. The lymphatics in the skin and the mucosae of the digestive, respiratory, and genitourinary systems are directly exposed to the action of agents in the environment that attack the integrity of the organism. The slightest damage to these tissues opens the lymphatics to foreign bodies, of which some are inert particles but others are active microorganisms.

These particles, whether inert or active, are carried by the lymph to the lymph nodes, where they come into contact with the phagocytes (fixed macrophages) of the lymphatic sinuses. These cells capture the foreign particles and prevent them from entering the blood stream.

Inert particles (coal, silica, etc.) accumulated in the lymph nodes eventually cause fibrous proliferation in these nodes. This process is especially prominent in the lymph nodes of the lung, because even in ordinary conditions of life the inspired air carries dust particles. It is even more prominent in workers in mines, stone quarries, and other industries in which there is a great deal of dust in the air. Marked fibrosis in a large number of lymph nodes causes the disease known as pneumoconiosis (Greek *πνεύμων*, lung, and *κονία*, dust), referred to in a preceding paragraph.

Innocuous microorganisms are digested by the phagocytes. Virulent microorganisms cause inflammation in the site of entry or the corresponding lymph node, or both. If the microorganisms are highly virulent, the first line of defense in the lymphatics is overcome and they pass into the blood, provoking general infection (sepsis).

The concentration of immune antibodies in the lymph entering and leaving a lymph node has been examined. These observations, together with others, have led to the belief that lymph nodes produce antibodies. The results are not sufficiently clear to have convinced all workers in this field, and the subject is still under discussion.

Malignant tumors also spread along the lymphatic system. Tumor cells released from the parent tumor are carried by the lymph and proliferate in the regional nodes, or pass into the blood stream and are distributed all over the body.

CEREBROSPINAL FLUID

The central nervous system (brain and spinal cord) is bathed by a special fluid known as the cerebrospinal fluid, which also fills the internal cavities, *i.e.*, the ventricles and ependymal canal.

The cerebrospinal fluid occupies a completely closed space, without any direct communication with the blood vessels or the lymphatic system. This space comprises two compartments: (*a*) the subarachnoid space; (*b*) the ventricular cavities and the ependymal canal. The former is external and the latter internal with respect to the nervous structures.

The subarachnoid space is situated between the visceral layer of the arachnoid and the pia, which is closely attached to the nervous tissue and dips into all the junctions and fissures. Numerous fine trabeculae join both membranes and give a spongy aspect to the subarachnoid space (Fig. 124). The walls of this space and the trabeculae are lined by a continuous layer of flat endothelial cells, similar to those of the intima of the blood vessels. Blood vessels in the subarachnoid space are surrounded by the arachnoid, which sometimes forms a complete "cuff" around them.

The subarachnoid space varies in size in different parts. In some places it is a narrow cleft; in others it

forms irregular cavities, which are in free communication with each other and with all the rest of the subarachnoid space and are known as cisternae. One of the largest of these cavities is the cisterna magna, placed between the medulla and the cerebellum. Another important cavity is formed below the spinal cord. It ends, together with the pia, at the level of the first lumbar vertebra, while the dura and arachnoid extend down to the second sacral segment. Lumbar puncture is the introduction of a needle into this space, through the skin and soft parts between two vertebrae, in order to withdraw cerebrospinal fluid or to inject a substance into it.

Spinal anesthesia is performed by injecting a local anesthetic (*e.g.*, procaine) into the subarachnoid space by lumbar puncture. By this means, lengthy operations on the abdomen and lower limbs can be performed painlessly and without the patient losing consciousness.

The ependymoventricular space evolves from the primitive neural canal of the embryo. It is made up of the ependymal canal, the fourth ventricle, the sylvian aqueduct, the third ventricle, and the lateral ventricles. All these cavities communicate with each other and are lined by the ependymal cells of ectodermic origin.

The two main compartments occupied by the cerebrospinal fluid communicate with each other at the level of the fourth ventricle through the foramina of Magendie and Luschka.
Fig. 124. Anatomical relations between the venous sinuses and the subarachnoid space. 1, venous sinus; 2, dura; 3, arachnoid villi; 4, subdural space; 5, cortical vein; 6, perivascular space; 7, subarachnoid space; 8, pia; 9, arachnoid. (*After Weed.*)

The blood vessels do not enter the subarachnoid space nor the internal cavities; the arachnoid or the ependymal membranes line their outer surface. Where an arteriole penetrates into the nervous tissue, the arachnoid and pia surround it and form a perivascular space, an extension of the subarachnoid space, which goes a short way into the depth of the nervous tissue (Fig. 124). In the ventricles the blood vessels in some places ramify profusely and form the chorioid plexuses, which seem to float in the ventricular cavity. They are covered by the ependymal lining and play an important part in the formation of the cerebrospinal fluid.

The subarachnoid space comes into intimate contact with the venous sinuses. In certain parts, fingerlike processes of the arachnoid, covered by the venous endothelium and the dura, project into the lumen of the sinus. The arachnoid villi (Fig. 124) thus formed

are submerged in venous blood, the subarachnoid space being separated from the blood stream by a very thin membrane. In the chorioid plexuses of the ventricles there is a similar situation, but in the opposite direction; the capillaries filled with blood are submerged in the cerebrospinal fluid, the blood being separated from the fluid by a very thin membrane. The chorioid plexuses play a fundamental part in the formation of cerebrospinal fluid, while the arachnoid villi do so in its reabsorption.

Table 21. Chemical Composition of Cerebrospinal Fluid

Inorganic substances	*Concentration, mg. per cent*	*Organic substances*	*Concentration, mg. per cent*
Sodium	335	Glucose	70
Potassium	106	Cholesterol	1
Calcium	53	Urea	15–25
Chloride	435	Proteins	10–25
Bicarbonate (CO_3H)	105	Total N	20
Phosphate (PO_4)	2	Fibrinogen	None

Chemical composition and physical properties. The total amount of cerebrospinal fluid has been calculated as 150 cc. This is the quantity of fluid that is found at a given moment, but it is continuously formed and reabsorbed, so that if a cannula is placed in the subarachnoid space much larger amounts can be collected. It is normally transparent and colorless; the specific gravity is 1.005. The protein content is only 18 mg. per cent, and as there is no fibrinogen, the fluid does not clot. Glucose is found in a concentration of 70 mg. per cent and sodium chloride about 700 mg. per cent. There are also small amounts of urea, creatine, cholesterol, etc. The average concentration of the principal substances in the cerebrospinal fluid is given in Table 21. There are few cells in the cerebrospinal fluid, mainly lymphocytes. The cell count is normally below 3 per cu. mm.

Formation and reabsorption of the cerebrospinal fluid. Cerebrospinal fluid is formed in the chorioid plexuses, the ventricles, and the perivascular spaces, especially those surrounding the capillaries of the pia. The process of formation is not well known; filtration and secretion seem to play a part in it.[1] Lymphagogues do not increase the formation of cerebrospinal fluid, but pilocarpine, which stimulates secretions, does; atropine and hyoscyamine suppress its formation.

[1] Obstruction of Monro's foramen provokes dilatation in the ventricle occluded; this does not occur if the chorioid plexus is extirpated.

There is a continuous flow of cerebrospinal fluid because of its incessant formation and reabsorption. Reabsorption takes place mainly through the arachnoid villi.[1]

The pressure of the cerebrospinal fluid is always higher than the pressure in the venous sinuses. Arterial blood pressure is an important factor in cerebrospinal fluid pressure, and reabsorption through the arachnoid villi is perhaps a simple process of filtration. Pressure in the cerebrospinal fluid, measured by lumbar puncture, is 6 to 12 cm. H_2O if the subject is lying down and 20 cm. H_2O if he is sitting up.

An obstruction in any part of the path followed by the fluid causes an increase of pressure upstream to the obstacle; therefore it continues to be formed even against pressures above those normally existing in the ventricles.[2]

Intravenous injection of hypertonic saline solution causes an immediate but transient rise in cerebrospinal fluid pressure, followed by a marked and prolonged fall. This is due to an increase in the osmotic pressure of the blood, which draws fluid from the tissues and cavities of the organism into the blood vessels. The escape of large quantities of fluid from the subarachnoid space causes the cerebrospinal fluid pressure to fall. The brain also loses water, and its mass diminishes. In neurosurgery hypertonic solutions are injected before opening the cranium so as to have more "space" for operating.

The cerebrospinal fluid is an important adjunct to the central nervous system, offering it support and adequate conditions for normal function.

SECTION THREE

Respiration

Under conditions of aerobiosis, cells need oxygen for the conversion of the energy chemically bound in foodstuffs into work, heat, etc. Oxygen has the functions of a food and should be considered as such. Respiration is therefore a metabolic or nutritional function.

Oxidation takes place within the cells by a process known as internal respiration. In unicellular organisms, oxygen from the environment diffuses directly into the protoplasm, and the CO_2 formed by oxidation diffuses out of the cell. In multicellular organisms with differentiated tissues, respiration by simple diffusion is not possible; oxygen is carried by the blood to the tissue fluids which bathe the cells, but since it is not very soluble in water or plasma, special respiratory substances (*e.g.*, hemoglobin) have been developed that can combine loosely with the oxygen and so transport it in the blood to the tissues.

The blood is loaded with oxygen in special organs. These are the gills in aquatic animals like fishes; the digestive tract and skin in certain amphibians; the lungs in birds, mammals, and other animals that live in an atmosphere of air (external respiration).

The gaseous product of respiration, CO_2, is eliminated in higher animals by an even more complicated mechanism of transport than that which carries oxygen to the tissues.

Respiration in mammals comprises (*a*) pulmonary or external respiration, which includes the exchange of gases in the alveoli of the lungs, respiratory movements which bring about the renewal of air in the lungs, and the nervous and humoral mechanisms regulating these movements; (*b*) transport of oxygen and CO_2 by the blood, and the mechanisms that control it; (*c*) utilization of oxygen by the cells, or internal respiration.

The different aspects of this function are closely interdependent and are linked with other functions such as the circulation, the activity of the nervous system, and the acid-base equilibrium.

CHAPTER 26

The Mechanics of Respiration

GASES ARE EXCHANGED between the blood and air through the walls of the alveoli. The blood and air in the lungs must be continuously renewed in order to maintain efficient conditions for this interchange. Air is renewed by thoracic and pulmonary expansion, causing inspiration, and retraction, causing expiration. The anatomic and functional properties of the thorax are such that all three of its diameters are increased during inspiration.

Respiratory movements are caused by the active contraction of the respiratory muscles and the passive effect of the elasticity of bony structures and the lungs. Both these factors are essential for respiration. The movements of the respiratory muscles are controlled by the nervous system.

To obtain a clear idea of the mechanics of the thorax, it is best to consider separately the bony structures, the respiratory muscles, and the thoracic contents.

BONY STRUCTURES OF THE THORAX

The bony structures of the thorax are the thoracic vertebrae, the ribs with their cartilages, and the sternum. Each rib with its cartilage makes up a costal arch; each pair of costal arches, with its corresponding vertebrae and the sternum, forms a costal ring. The ribs increase in length from the first to the seventh, which is the longest; then decrease to the twelfth, which is the shortest. The anterior extremities of the last two ribs (the floating ribs) are unattached, and they do not take an active part in respiration. From a functional point of view, they form part of the abdominal wall.

The spinal column is extended and increases in length during inspiration, but to simplify the study of the mechanics of respiration, it can be considered as a rigid structure. It articulates with the ribs by two joints: one formed by the head of the rib, which articulates with two contiguous vertebrae, and the other formed by the articulation of the costal tuberosity with a transverse process. The distance between the centers of the two articular surfaces in the sixth rib is from 25 to 30 mm. Because of this anatomical arrangement the ribs have only one movement—that of rotation around an axis that unites the functional centers of both costovertebral joints (Fig. 125). Slight movements due to the elasticity of the ligaments or ribs can be discounted. The transverse and anteroposterior diameters of the chest are increased on contraction of the elevator muscles as a result of the direction of the axis of rotation, the form of the ribs, and their downward and forward position. Figures 125 and 126 show the changes in position of the sixth rib during inspiration and expiration. A better idea of these movements can be obtained by taking a rib (*e.g.*, the sixth), placing it in the position it would occupy in the thorax, then moving it slightly on its axis of rotation. It can easily be seen that the movement due to inspiration causes that part of the rib which is farthest from the mid-line to move even farther, while the anterior extremity moves forward.

The sternum moves with the ribs, and because of the greater motility of the middle ribs it is projected upward and forward during inspiration. The ribs do not all have the same degree of movement, because of their differences in length, form, and attachment to other anatomical structures.

The thorax can be compared to a truncated cone, which has a wider transverse than anteroposterior diameter. It can be divided functionally into three parts: the operculum, the

upper costal mechanism, and the lower costal or diaphragmatic mechanism.

The operculum is formed by the first pair of ribs and the manubrium. On inspiration the operculum rises, the anteroposterior diameter increases, and the manubrium is projected forward; the transverse diameter varies only slightly or not at all. Two important factors in this movement are the torsion of the first costal cartilage and the manubriosternal joint; this joint is movable until fifty or sixty years of age. The operculum acts especially on the apexes of the lungs.
Fig. 125. Diagram showing movements of the sixth rib. The broken line indicates the position of the rib in inspiration; the solid line, its position in expiration.

The upper costal mechanism is formed by the costal rings corresponding to the second to fifth ribs and expands the upper part of the lungs. The lower costal mechanism is formed by the sixth to tenth ribs and expands mainly the inferior lobes of the lungs. As has already been mentioned, the last two ribs are not functionally part of the thorax.

RESPIRATORY MUSCLES

The contraction of the respiratory muscles causes active movement of the ribs, while passive movement is due to thoracic and pulmonary elasticity. Muscular contraction during respiration can be observed by simple inspection, by registration of the muscles' shortening by a myograph, or by a record of the electrical phenomena of their activity. The last, more modern, method is the most suitable, as it registers phenomena without traumatism, only requiring the introduction of needle electrodes into the muscles. This method demonstrates the progressive increase of nerve impulses during inspiration or expiration until they are suddenly interrupted by the initiation of the opposite act.

Inspiratory muscles. These muscles raise the ribs. They can be divided into principal muscles and accessory or emergency muscles. Only the former are used for normal inspiration; in forced inspiration the latter also take part.

The principal inspiratory muscles are the levatores costarum, the serrati postici superiores, the external intercostals, and the diaphragm. The first two groups are inserted on the spinal column and the ribs, and on contracting they raise the ribs. The external intercostals are inserted on two contiguous ribs and the corresponding cartilages; the fibers have a forward and downward direction. Their action is represented diagrammatically in Fig. 127. Records of the action potentials show that in quiet breathing the ribs are raised mainly by the contraction of the external intercostals and the interchondral part of the internal intercostals. Normal inspiration in the dog can be maintained by the contraction of these muscles alone.
Fig. 126. The same diagram as in Fig. 125, seen along the vertical axis of the thorax.

The accessory inspiratory muscles act only in forced or dyspneic inspiration. This can be demonstrated by a simple observation: A thumb and finger are placed over the sternocleidomastoid muscles. During quiet breathing no change in tension is felt, but on making a sudden deep inspiration the contraction of the muscles

can be felt below the skin. These muscles and the scaleni raise the upper ribs.

The major and minor pectoral and serrati antici majores muscles raise the ribs when the shoulder and arm have been previously fixed. The shoulder girdle is fixed by the levatores angulorum scapulorum, trapezii, and rhomboidei. Patients in an attack of asthma or other dyspneic condition instinctively grip some firm object such as the head of the bed, so as to fix the upper limb and thus permit the action of the accessory respiratory muscles.
FIG. 127. Diagram showing the action of the external intercostal muscles. The vertical bars represent the vertebral column and the sternum; the oblique bars show the ribs in expiration (solid line) and in inspiration (broken line). The external intercostal muscles shorten on contraction and pass from the position *EE'* to *II'*, raising the ribs.

The diaphragm is the principal inspiratory muscle, and it can maintain adequate respiration when all the other respiratory muscles have been paralyzed. This can be shown in animals by cutting the spinal cord immediately below the origin of the phrenic nerve, an operation which paralyzes nearly all the other inspiratory muscles. Cases of section of the spinal cord at this level have demonstrated that in man also the diaphragm has a similarly predominant part in inspiration.

The central part of the diaphragm is a tendinous membrane. Its projection on the chest wall corresponds to the sixth chondrosternal joint. It is fixed to the mediastinum by the fibrous pericardium. Muscle fibers are inserted on all the periphery of this tendinous membrane. Some of these fibers have a backward and downward direction, and their other end is inserted on the lumbar vertebrae; they form the crura of the diaphragm. The rest of the muscle fibers form a dome-shaped structure descending to insertions on the lower ribs and the sternum. On the right side the diaphragm covers the upper surface of the liver; its highest point is projected on the chest wall at the level of the fourth intercostal space in the axillary line, in normal expiration. The left side is 14 to 27 mm. lower than the right (Figs. 128 and 129).

The dome shape is due mainly to the negative intrathoracic pressure which raises the diaphragm and draws it laterally against the thorax, closing the costophrenic angles. Abdominal pressure is an accessory factor. The diaphragm still keeps its domelike position in the cadaver after the abdomen has been opened and the viscera removed, but it becomes flaccid and is no longer dome-shaped if the thorax is also opened, causing the lungs to collapse. Muscular tone and active contraction of the diaphragm lower the dome. The mechanics of the diaphragm are not simple. The only fixed insertion of its fibers is that on the lumbar vertebrae. Contraction of the crura pulls the diaphragm down, lengthens the vertical diameter of the thorax, and causes the base and hilum of the lungs to descend. The other insertions are all made on mobile structures and it will be necessary to consider the results when these are fixed or mobile. When the tendinous center is fixed, the costosternal fibers raise the lower ribs, and like the other muscles that have the same effect on the upper ribs, they increase the transverse diameter of the thorax. If, on the contrary, the costosternal insertions are fixed, the diaphragmatic dome descends, and the vertical diameter is increased. In quiet breathing the diaphragm descends only slightly. Thus contraction of the diaphragm increases the three thoracic diameters.

The cross-sectional area of the thorax at the level of the diaphragmatic dome is approximately 250 sq. cm. If the movement of the diaphragm is compared to a piston, a descent

of 10 mm. will increase the thoracic volume by 250 cu. cm; *i.e.*, an amount equivalent to half the tidal volume (see "The amount of air in the lungs," page 250). This calculation is not accurate, because the movements of the diaphragm are not the same as those of a piston; nevertheless it gives an approximate idea of the importance of the diaphragm in respiration.
FIG. 128. X-ray of thorax in normal expiration.

As the diaphragm descends it exerts pressure on the abdominal viscera, which in their turn move the abdominal walls. Thus normal inspiration increases the diameters not only of the thorax but also those of the abdomen, and the type of respiration is known as "thoracic" or "abdominal" according to whether the contraction of the thoracic muscles or the diaphragm is most prominent.

In paralysis of the diaphragm it behaves as a passive membrane and ascends during inspiration; thus while the thorax widens, the abdominal girth diminishes. This is known as "paradoxical" respiration.

Expiratory muscles. The ribs are lowered by the contraction of the interosseous part of the internal intercostals serrati postici minores and the triangular muscle of the sternum. Contraction of the muscles of the abdominal wall compresses the viscera and by this means exerts pressure and raises the diaphragm. In normal quiet breathing expiration is mainly passive; thoracic and pulmonary elasticity brings the thorax and its contents back to a position of elastic equilibrium at the end of a normal expiration.

The costophrenic angles. Part of the diaphragm is pressed against the thoracic wall during expiration; the angle thus formed is the costophrenic angle. On contraction of the diaphragm the curvature of its dome tends to
FIG. 129. X-ray of thorax of the same person in forced inspiration. Observe the increase in the transverse and vertical diameters of the thorax, the descent of the diaphragm, and the increase in the costophrenic angle.
FIG. 130. Diagram of the anteroposterior projection of the costal and diaphragmatic pleura in expiration and in forced inspiration. Tracings made from the x-rays of Figs. 128 and 129.

diminish because of the shortening of the muscle fibers, thus separating the diaphragm from the thoracic wall. In expiration the diaphragm is pressed against the thoracic wall over an area of 6 to 8 cm. in width; in inspiration, as the diaphragm separates from the wall and the angle opens, the lung descends into it.

Radiography shows these changes in the position of the lung (Figs. 128, 129), which can also be demonstrated by percussion of the base of the thorax. The inferior limit of pulmonary resonance descends in forced inspiration by four fingerbreadths.

THE LUNGS

The lungs and other thoracic viscera (heart, blood vessels, etc.) are subject to passive changes caused by the expansion and retraction of the thoracic wall.

Thoracic and pulmonary elasticity. Elasticity is the capacity of a strained body to recover its shape and size after the external forces that strain it cease to act. Elasticity varies in different bodies, and if the strain exceeds it, the original shape is not recovered.

The thoracic wall is elastic; its resting position is that of normal expiration. The elastic force must be overcome during inspiration, so that expiration is mainly due to elastic rebound. In forced expiration the expiratory muscles must overcome the elastic force; in this case, the beginning of inspiration is accompanied by elastic rebound.

The lungs are elastic structures permanently distended under normal conditions, but if the thorax is opened and air penetrates into the pleural cavity, the lung collapses and is reduced to a small mass at the hilum. This is observed not only in living subjects but also after death.

Pulmonary elasticity can be measured in the human cadaver by placing a tightly fitting cannula in the trachea and connecting it with a manometer. When the pleural cavity is opened, the lung retracts and the pressure in the trachea rises 6 to 7 mm. Hg (*i.e.*, 80 to 95 mm. H_2O). If the initial position is that of expiration, the pressure rises only 3.9 mm. Hg (53 mm. H_2O); it rises 9.4 mm. Hg (130 mm. H_2O) if the lung has been distended in inspiration. The difference in elastic strain between inspiration and expira-

FIG. 131. Diagram demonstrating pulmonary elasticity. The elastic recoil of the lung tends to reduce the size of the lung in the sense indicated by the arrows. This produces a "negative" pressure in the pleural cavity, which is measured by puncturing the pleural cavity and connecting the needle with a manometer.

tion is therefore equivalent to a pressure of 5.5 mm. Hg. Pulmonary elasticity tends to reduce the volume of the lungs, and the inspiratory muscles must overcome it to distend them. Expiration, on the contrary, is favored by the pulmonary elastic force and in normal conditions is mainly passive.
FIG. 132. X-ray of a case of pneumothorax. Air has penetrated into the left pleural cavity, the lung on that side has collapsed and is reduced to a small mass around the hilum. The heart is displaced toward the right. The diaphragm is lower on the left side than on the right because there is no "negative" pressure, owing to the absence of the elastic recoil of the lung.

Negative intrathoracic pressure. Pulmonary elasticity can also be demonstrated by puncturing the pleural cavity with a needle of wide bore and connecting it with a manometer (Fig. 131). Pressure in the pleural cavity is seen to be below atmospheric pressure and is usually called the "negative intrathoracic" or "negative intrapleural" pressure. This negative pressure is due to (*a*) the elasticity of the lungs; (*b*) the resistance with which the thoracic wall opposes this elasticity. Negative pressure is from 5 to 8 mm. Hg (70 to 110 mm. H_2O) in expiration and from 10 to 15 mm. Hg (135 to 200 mm. H_2O) in inspiration. Even in maximum expiration the lung is still submitted to elastic stress. Negative pressure maintains the domelike position of the diaphragm and also favors the entrance of blood into the large veins of the thorax.

Intrapleural pressure becomes positive (*i.e.*, above atmospheric pressure) when an expiratory effort is made while keeping the glottis closed, as in the act of defecation. This positive pressure causes several changes in the dynamics of the circulation.

Pneumothorax. If air penetrates into the pleural cavity accidentally or is introduced for the purpose of experiment or treatment, the lung collapses. The condition is known as pneumothorax (Fig. 132); it is called "open pneumothorax" when the wound in the lung or the thoracic wall remains open and lets the air circulate through it; otherwise it is called "closed pneumothorax." This condition causes severe disturbances in respiratory mechanics and in circulatory dynamics. The diaphragm is no longer drawn into the thorax by the elastic force of the lung, so it loses its domelike shape on the side corresponding to the pneumothorax (Fig. 132). The mediastinum is not a rigid structure, so it is pulled, together with the organs it contains, toward the normal side by the elastic effect of the normal lung (Fig. 132). The entrance of air is diminished not only in the collapsed lung, but also in the normal one, because its volume is decreased by the deviation of the mediastinum.

Unilateral pneumothorax is well tolerated in normal, quiet, physiologic conditions, and it is frequently provoked for the treatment of pulmonary tuberculosis. When there is anoxia such as that due to high altitude, decompensated cardiac disease, pneumonia, etc., pneumothorax has serious effects (dyspnea, cyanosis) and may even cause death.

In an open pneumothorax the severity of the condition depends on the size of the pleural opening. The ratio of air entering the lung to air entering the pleural cavity is the same as the ratio of the cross section of the trachea to the cross section of the pleural opening. If the cross section of the wound is equal to the cross section of the trachea, equal volumes of air enter the lung and the pleural cavity. In this case expansion of the thorax to twice that of normal inspiration will maintain a normal volume of tidal air. The size of the wound compatible with life will therefore depend on the vital capacity of the patient. If maximum expiration and inspiration

do not result in a normal volume of tidal air, the patient will be in danger of asphyxia. In subjects with a small vital capacity, an open pneumothorax is a more severe condition than in subjects with a large vital capacity. In the course of thoracic operations, artificial respiration by rhythmic insufflation should be kept up as long as the pleura is open; if only a small wound is made, however, this may not be necessary. Adhesions that bind the lung to the thoracic wall prevent the total collapse of the lung and diminish the severity of the symptoms of pneumothorax.

The decrease in the negative intrathoracic pressure hinders the entrance of blood into the large thoracic veins; therefore there is stasis in the extrathoracic veins, and the venous return to the heart diminishes.

An open pneumothorax causes considerable loss of heat and may be followed by a rapid fall in body temperature.

The movements of the lung. The total cross section of the respiratory tract increases progressively as the bronchi divide, so that it can be represented by a cone, with the apex in the trachea and the base in the alveoli. The total alveolar surface is approximately 100 sq. m.

The bronchi divide successively down to the terminal bronchioles, which have a smooth-muscle layer, the contraction and relaxation of which modify the amount of air going into or out of the alveoli. Terminal bronchioles branch out into respiratory bronchioles, so called because they have alveoli in their walls. The alveolar ducts open into the respiratory bronchioles. These ducts lead to the atria into which the air sacs open. The walls of the air sacs are made up of alveoli, but alveoli are also found in the walls of all the air tubes smaller than the terminal bronchioles (Fig. 133).

The expansion of the lungs is due to lengthening and dilatation of the fine branches of the air passages below the terminal bronchioles. The most distensible parts are the alveolar ducts; probably the alveoli do not change much in volume.

The lung is not dilated uniformly in all its parts during inspiration. The hilum, formed mostly by bronchi and blood vessels, has only slight distensibility. The middle of the lungs, where the bronchi and blood vessels ramify and where there is some parenchymatous tissue, is moderately distensible. Distensibility is at a maximum near the surface of the lung down to 2.5 to 3 cm. below this surface. As a whole the lung behaves more like a bellows than like a distensible sac.

The different parts of the lung do not expand to an equal extent in inspiration. The lower lobes expand more than the upper ones. The apex has not a very active part in respiration; in forced inspiration it is contracted and in forced expiration it is dilated. Two other regions, the mediastinal and dorsal surfaces, are not expanded much in inspiration. The diaphragmatic and costosternal surfaces expand most.
FIG. 133. Diagram of a pulmonary lobule. Three acini connected to a respiratory bronchiole are shown. The air sacs with the alveoli open into the atria and alveolar ducts. (*According to Miller.*)

The thoracic wall and the lungs move simultaneously, but the pulmonary and parietal pleurae slide on each other. The hilums move downward in inspiration, because of the descent of the diaphragm, and pull down the trachea. This can be easily seen by observing the descent of the larynx in inspiration. The displacement of the pulmonary surface varies in the different parts; it is not marked in the apexes, nor in the dorsal surface, but is considerable in the lower part of the lung, especially in the region of the

costophrenic angles, into which the lungs expand.

Pressure in the airways. The air passes in and out of the lung as a result of rhythmic changes in pressure, which can be easily measured and registered. In quiet breathing the difference in pressure between the atmosphere and the air in the lungs is only 2 to 4 mm. Hg, but in forced breathing it is much higher. A forced inspiration through a tube connected to a manometer can produce a negative pressure of −75 to −147 mm. Hg; a forced expiration can raise the pressure to +105 and even +256 mm. Hg. (These extreme figures are exceptional.) The maximum expiratory effort is greater than the maximum inspiratory effort. Expiration is used for voice production and to remove foreign particles from the respiratory tract by coughing, etc.

FIG. 134. Subdivisions of lung volume. (*Federation Proc., vol. 9, p. 602, 1950.*)

Circulatory changes caused by respiratory movements. Pressure in the pleural cavity is always negative, even in expiration, except when an expiratory effort is made keeping the glottis closed. This negative pressure assists the inflow of blood into the large thoracic veins and causes a negative pressure in the large veins of the neck. (There is danger of air embolism if these veins are wounded.) Negative pressure is greater in inspiration; therefore in inspiration more blood as well as more air flows into the lungs. This is an interesting example of functional coordination.

The amount of air in the lungs. (Fig. 134.) At a meeting held in 1950[1] the definitions of lung volumes and the terminology used were discussed in order to provide uniformity in the literature. It was recommended that the word "air" be replaced by "volume," "complemental" or "complementary air" by "inspiratory reserve volume," and "supplemental" or "reserve air" by "expiratory reserve volume," as these terms have a functional significance and are more easily remembered. A systematic set of symbols for the different variables in respiration physiology was also recommended. Subdivisions of the lung volume are represented in Fig. 134.

The following are the average figures for the lung volumes:

	Liters
Vital capacity:	
In men	3–4
In women	2–3
Inspiratory reserve volume, resting	2
Expiratory reserve volume, resting	1.5
Residual volume	1.5
Tidal volume	0.5

These volumes vary with the conditions of the subject, *e.g.*, rest, activity, etc. The residual volume varies with inspiratory or expiratory effort, partly because of changes in the amount of blood in the thorax, which increases with inspiratory effort and decreases with expiratory effort. The residual volume varies inversely to the amount of blood in the thorax.

The tidal volume is the air entering and leaving the lungs in a respiratory cycle. Of the total 500 cc., only about 360 cc. reaches the alveoli and takes part in hematosis. The rest (approximately 140 cc.) remains in what is called the dead space, *i.e.*, the large bronchi, trachea, larynx, and nasal cavities. When masks are used, *e.g.*, for anesthesia or protection against toxic gases, the volume of the dead space increases. The tidal volume must then be increased in order that sufficient fresh air may reach the alveoli, and therefore the pulmonary ventilation must be increased.

Changes in the volume of the dead space. The dead space is that part of the respiratory tract which has no alveoli. It therefore extends down to, and includes, the terminal bronchioles. The volume of air in the dead space varies, because the airways are not rigid structures. During inspiration the respiratory tubes are lengthened and dilated, especially in deep breathing.

The "physiologic" or "effective" dead space is the total space of the respiratory tract which, immediately before expiration, is filled with atmospheric air unmixed with alveolar air, *i.e.*, air that has not reached the region of

[1] *Federation Proc.*, **9**, 602, 1950.

gaseous exchange. The physiologic dead space can be calculated by subtracting the alveolar expired air from the total volume of expired air. Alveolar expired air is calculated from the concentration of CO_2 in expired and in alveolar air. For example, the total volume of expired air is 485 cc.; CO_2 concentration in expired air is 4 per cent and in alveolar air it is 6 per cent. The alveolar expired air in this case is

$$485 \times 4/6 = 323 \text{ cc.},$$

and the physiologic dead space is

$$485 - 323 = 162 \text{ cc.}$$

Spirometry. The volume of expired air and vital capacity are measured by instruments called spirometers, of which there are several models. Hutchinson's spirometer consists of a metal cylinder of adequate capacity, which is filled with water; a metal tube pierces the bottom of the cylinder, to which it is soldered, and rises above the level of water. This tube is connected by rubber tubing with a mouthpiece into which the subject breathes. The spirometer bell is another metal cylinder of slightly smaller diameter than the first one, into which it fits. It is completely submerged in the water (the air within it escapes through the metal tube) and its weight is accurately balanced by a counterweight. The subject breathes out by the mouthpiece into the spirometer; and the air raises the bell. The volume of air is read on a scale along which an indicator attached to the bell moves. To measure the air breathed out during several minutes, a system of valves is added so that atmospheric air is inspired and the expired air is collected in the spirometer or passed through a gas meter.

Vital capacity. The volume of air expired by a maximal expiration following a maximal inspiration has been given the name of vital capacity.[1] It is approximately 3 to 4 liters in men, exceptionally 5 to 6 liters; in women it is usually 2 to 3 liters.

The determination of the vital capacity is frequently used in armies and athletic clubs to estimate indirectly the capacity of an individual for physical effort. Vital capacity decreases when the elasticity of the thorax, or the lung, or both diminish (pleurisy, emphysema, sclerosis of the lung, ossification of the costal cartilages, etc.). Pain in the thorax or near the thorax (pleurisy, peritonitis) also diminishes vital capacity, because respiratory movements increase the intensity of pain. Several factors have an influence on vital capacity: *e.g.*, posture (it is greater when standing up than lying down), age (it increases up to twenty or thirty years, and later diminishes), sex, race, occupation, etc. It can be increased by training, and in athletes it is considerably above the average.

The relation between vital capacity (VC) and other bodily measurements has been established:

$$\frac{(\text{Weight})^{0.72}}{VC} = K_1$$

$$\frac{(\text{Sitting height})^2}{VC} = K_2$$

$$\frac{\text{Chest circumference}}{VC} = K_3$$

The average normal values for these constants are

$$K_1 = 0.69,\ K_2 = 1.85,\ K_3 = 2.41.$$

$$\frac{VC,\ \text{in liters}}{\text{Body surface, in sq. m.}} = 2.61\ (\text{men}),\ 2.07\ (\text{women})$$

Standing height multiplied by 22 to 24 gives the vital capacity in cubic centimeters in men; the height should be multiplied by 20 in women and 15 in children. Vital capacity is more closely related to height than to weight in fat and thin persons.

Altamira[1] has found the following average values in 431 healthy men eighteen to thirty-eight years old:

$$\begin{aligned}\text{Vital capacity} &= (\text{Body surface} \times 1{,}600) + 1{,}225\\ &= (\text{Standing height} \times 4{,}860) - 4{,}220\\ &= (\text{Weight} \times 18) + 2{,}900\\ &= (\text{Chest circumference} \times 42.5) + 440\end{aligned}$$

Of all these correlations the most reliable is that with the body surface.

Pulmonary ventilation. About one-third of the 500 cc. of the tidal air remains in the dead space; the rest reaches the alveoli, where it mixes with the air already in the alveoli, *i.e.*, the expiratory reserve volume plus the residual volume, approximately 3,000 cc. (Fig. 134). These volumes vary according to the individual and the conditions which obtain (rest, work, emotion, etc.), but on an average the volume of fresh air reaching the alveoli is approximately

[1] Unless otherwise specified the term "vital capacity" signifies Hutchinson's vital capacity as here defined. Other "vital capacities" are less frequently referred to.

[1] ALTAMIRA, J. DEL V., Estudios sobre la Capacidad Vital de los Estudiantes de Medicina de Córdoba, thesis for M. D., Buenos Aires, 1941.

10 to 12 per cent of the volume of air in the lungs at the end of expiration. In normal breathing at rest, therefore, one-tenth to one-eighth of the air in the lung is renewed at each inspiration. This proportion is known as the ventilation coefficient; it increases proportionately to the depth of breathing.

In certain circumstances it is useful to know the number of respiratory movements needed to renew all the air in the lungs. For instance in anesthesia with gases using the "closed-circuit" method, it is desirable to eliminate almost completely the nitrogen in the lung. The usual procedure is to start anesthesia with an "open circuit," *i.e.*, breathing the expired air out into the atmosphere, and to close the circuit only after about ten respiratory movements have been made. One method of knowing when a certain gas such as hydrogen has been completely eliminated is to have the subject inhale one breath of hydrogen and then to examine the hydrogen concentration in samples of expired air taken at each successive breath. It will thus be seen that in 6 to 10 respiratory movements almost all the hydrogen has been expelled from the lungs.

Ratio of pulmonary ventilation to oxygen absorption. This ratio, introduced by Anthony, refers to the liters of air breathed for each 100 cc. of oxygen absorbed by the lungs. The average values found in normal subjects are 2.75 liters (Anthony) or 2.44 liters (Knipping), the extremes being 1.68 and 4.5 liters. There are no considerable daily variations in the same subject; values found during exercise are similar to those found during rest; and the addition of oxygen to the inspired air does not alter the ratio. These observations show that, with adequate oxygen tension, CO_2 tension is the principal factor governing pulmonary ventilation.

The determination of this constant is of special value in cases of functional disturbance of the lung, particularly when the ventilation of each lung is considered separately (see "Bronchospirometry," below). It is more valuable as a sign of respiratory efficiency than the determination of the vital capacity. Normal pulmonary ventilation and vital capacity can be found in cases in which the ratio of pulmonary ventilation to oxygen absorption is high, indicating poor oxygen absorption, which is usually due to disturbances in the lungs or the pulmonary circulation.

Pneumography. This consists in taking a record of the respiratory movements (a pneumogram) by means of special instruments known as pneumographs. Usually the changes in the mid-thoracic perimeter are registered. The records show that expiration lasts longer than inspiration. If the respiratory rate is below 15 per minute, a short expiratory pause is recorded, but with higher frequencies this pause is no longer observed.

Respiratory frequency. The rate of respiration varies in normal subjects according to the species and is influenced by age, sex, size or height, work and rest, sleep, digestion, etc.

Table 22. Average Respiratory Frequency at Rest at Different Ages

Age	*Frequency per Minute*
Newborn	60–70
5 years	26
15–20 years	20
25–30 years	16

Respiratory frequency is a function of the metabolic rate. As the metabolic rate increases, so does the need of oxygen, and the rate of respiration also increases to supply this greater demand. In basal conditions animals of small size have a higher respiratory frequency than larger animals. The latter have a relatively smaller body surface with respect to weight, and a lower basal metabolic rate than the former. Frequency of respiration increases whenever the oxygen consumption increases; *e.g.*, during exercise, fever, etc.

Respiratory minute volume. The respiratory minute volume is obtained by multiplying the tidal volume by the respiratory frequency; it is 6 to 8 liters in a normal adult man when resting. This is the total pulmonary ventilation, but these figures do not always give a correct idea of its efficiency. For example, superficial respiration of great frequency does not ventilate the lungs adequately in spite of a large respiratory minute volume, because only a fraction of the tidal volume reaches the alveoli; to determine the alveolar ventilation, the dead space corresponding to each respiratory movement must be subtracted from the total ventilation.

Pulmonary ventilation, increased by a higher respiratory frequency and larger tidal volume, is also affected by a third factor, *i.e.*, an increase in respiratory surface,[1] which shows itself by an increase in total lung volume and in residual

[1] PEYSER, E., A. SASS-KORTSÁK, and F. VERZÁR, *Am. J. Physiol.*, **163**, 111, 1950; VERZÁR, F., *Ciencia e invest.*, 7, 303, 1951.

functional capacity. This has been demonstrated in several species, including man, in response to oxygen want caused either by physical exercise or by a fall in the oxygen partial pressure in inspired air. The greater lung volume is due, according to Verzár and his associates, to relaxation of the smooth muscles of the bronchi, brought about by sympathetic discharges, and to an increase in inspiratory muscle tonus. The larger alveolar surface facilitates diffusion of oxygen from the alveolar air to the blood. CO_2 in the inspired air, in spite of increased ventilation, had no effect on total lung volume.

Respiration is rhythmic when the respiratory movements are of the same depth and duration. Disturbances in respiratory rhythm will be considered in Chap. 33.

THE PHYSIOLOGY OF THE BRONCHI

The large and median bronchi are simply air tubes. The cartilage in their walls does not form complete rings, but it is sufficient to keep them open and to prevent any considerable change in their diameter. The small bronchi have no cartilage but have a layer of smooth muscle (Reisseissen's muscle). Contraction and relaxation of these muscle fibers modify the diameter of the bronchioles and thus the amount of air entering the alveoli, alveolar ventilation, and alveolar gas tensions. Moreover, a deep inspiration performed when the bronchioles are constricted causes alveolar pressure to fall considerably more than during normal inspiration, and thus may produce transudation of plasma from the pulmonary capillaries into the alveoli.
Fig. 135. Record of lung volume and blood pressure (upper and lower tracings respectively). 1, injection of morphine: the bronchioles contract and the lungs expand less at each respiratory movement; 2 and 3, adrenaline is injected and as the bronchioles relax more air enters the lungs and they expand more. Note the increase in blood pressure aftereach injection of adrenaline. Time in 4 sec. (*Jackson, D. E., "Experimental Pharmacology," Mosby, St. Louis, 1917.*)

Methods for studying bronchial musculature. Contraction of the bronchiolar muscles diminishes the amount of air flowing into the lungs; relaxation has the opposite effect. Therefore when the lungs are functioning rhythmically and at constant pressure, the volume of the lungs diminishes when the bronchiolar muscles contract and increases when they relax. The volume of the lung can be recorded by introducing into the pleural cavity a tube connected with a Marey tambour. At each insufflation the lungs expand. If a bronchioconstrictor substance is injected, expansion is considerably reduced (Fig. 135, 1); it can again be increased by injecting a bronchiodilator substance (Fig. 135, 2 and 3).

A variant of this method consists in measuring the pressure of the air in the lung which is being expanded rhythmically by a constant volume of air sent into the lung either by (*a*) insufflation into the trachea, (*b*)

compression of the thorax, or (*c*) compression of the lung placed in a plethysmograph.

In another method the isolated lung of a rabbit or guinea pig is perfused at constant pressure with Ringer's fluid, which is made to flow in through the trachea and bronchi and to flow out through minute openings made on the outer surface of the lung by scratching it with a needle. The amount of fluid passing through the lung in unit time depends on the diameter of the bronchioles. Bronchioconstrictor agents added to the perfusion fluid diminish or even stop the flow through the lungs.

Visceral motor nerves control the movements of the bronchial muscles. Stimulation of the parasympathetic contracts these muscles, and they are relaxed if the sympathetic is stimulated. Parasympathomimetic drugs (*e.g.*, acetylcholine) have a constrictor effect. Sympathomimetic drugs (*e.g.*, adrenaline) and parasympatholytic drugs (*e.g.*, atropine) relax the bronchiole muscles only if they are previously in a state of contraction; in normal conditions they have no effect. This observation shows there is no vagal tone, *i.e.*, the bronchiole muscles are not maintained in tonic contraction by vagal impulses, at least in experimental conditions. During an attack of asthma the bronchial muscles are contracted. Frequently it is possible to produce immediate relief by injecting a bronchiodilator agent (adrenaline, atropine, etc.).

EXPLORATION OF THE LUNG

The condition of the lungs can be examined by several methods. Percussion of the thorax over the parts of the lungs filled with air gives a resonant sound. On auscultation a peculiar rustling sound, the "vesicular murmur," is heard when air penetrates into the alveoli; it is an inspiratory sound, and increases in deep inspiration. It is not heard when air does not enter the alveoli. A murmur, due to the passage of air in the trachea and large bronchi, is heard if the ear is placed over the manubrium of the sternum or the stethoscope over the larynx. This murmur is normally not heard over the lateral walls of the thorax, but it can be heard in certain diseases of the lung, *e.g.*, pneumonia.

X-rays (radioscopy and radiography) are frequently used to determine the condition of the lungs and in the study of the mechanics of respiratory movements (Figs. 128, 129, and 132).

Bronchospirometry. The functions of each lung can be examined separately, thanks to the methods of bronchospirometry introduced by Jacobeus in 1932 and improved by Gebauer in 1939. The latter designed a catheter made of flexible rubber with two tubes. The longer of the two tubes is introduced into the left bronchus and adapted to it so that air can go into and come out of the left lung only through this tube. The shorter tube is adapted to the trachea, through which only air going and coming from the right lung circulates. The external ends of the two tubes are connected with two Benedict-Roth spirometers.

Oxygen consumption, respiratory minute volume, tidal volume, pulmonary ventilation, oxygen consumption ratio, vital capacity, inspiratory and expiratory reserve and residual volumes, and respiratory gaseous exchange for each lung can be determined by this method. This information is valuable to determine the respiratory deficiency in a diseased lung and the degree of compensation accomplished by the healthy lung, before applying certain therapeutic measures, such as artificial pneumothorax or the surgical removal of a lung or part of a lung.

In normal subjects lying on one side, the vital capacity of each lung varies according to the degree of compression to which it is submitted. If the curvature of the spine is such that the upper lung is compressed, the lung on the lower side has a greater vital capacity, respiratory minute volume, and inspiratory reserve volume and absorbs more oxygen.

The composition of alveolar air and the respiratory quotient of one lung can be different from that of the other lung in certain cases of pulmonary disease. The alveolar air collected by the usual method is a mixture of the alveolar air from both lungs.

THE UPPER RESPIRATORY TRACT

1. *Nasal cavities.* The alae nasi are dilated at each inspiration in some species (rabbit, horse). In man this occurs only when there is dyspnea.

The nasal mucosa plays an important part in modifying the inspired air as it passes through the nasal cavities, and thus it protects the more delicate membranes of the lung. The surface of the mucosa is increased by being spread out over the conchae. It is provided with a rich vascular network, and it secretes continuously. Small dust particles are retained by the secretions of the mucosa and by the nasal hairs. Evaporation of nasal secretions humidifies the inspired air. The temperature of the air is raised as it passes over the well-vascularized mucosae.

There are many nerve endings in the nasal mucosa. Those of the trigeminal nerve are stimulated by irritant vapors in the inspired air. A reflex is thus initiated which inhibits inspiration and provokes bradycardia. Section of the vagus nerve or injection of atropine prevents the reflex bradycardia. Olfactory nerve endings are situated in the upper part of the nasal mucosa; these will be considered in Chap. 75, when discussing the sensation of smell.

2. *Pharynx.* This is merely an air passage and has no other special function in respiration. It descends during inspiration, together with the larynx, being pulled down by the lungs, which expand downward as the diaphragm contracts.

3. *Larynx.* The glottis is dilated during inspiration by the separation of the vocal cords. When the vagus nerve or its recurrent laryngeal branch is paralyzed, the vocal cords remain flaccid and in accelerated breathing inspiration is disturbed. In young animals bilateral paralysis of the vocal cords causes death by asphyxia.

ARTIFICIAL RESPIRATION

When respiration ceases (drowning, carbon monoxide asphyxia, electrocution, etc.) or there is danger of respiratory failure, the air in the lungs must be renewed by artificial respiration. Many methods have been proposed, but only a few will be mentioned here.

Methods of artificial respiration can be divided into mechanical and manual. There are two types of mechanical methods, the so-called "resuscitators" and the iron lungs. A resuscitator[1] is an apparatus which produces ventilation of the lung by providing rhythmic variations of pressure through a face mask or tracheal catheter. Some completely mechanical models, *e.g.*, the spiropulsator, allow changes in respiratory rate and volume, length of inspiration, and length of inspiratory pause. In asphyxia of the newborn, oxygen (or 95 per cent oxygen + 5 per cent CO_2) is rhythmically insufflated through a soft rubber catheter inserted in the trachea; the pressure should not rise above a few centimeters of water in order not to damage the delicate lung tissues.

There are several models of "iron lung." Such an apparatus consists of a metal tank in which the patient is placed with the head protruding through a rubber collar. The pressure of the air in the tank is alternately increased and diminished by an electric pump. The alternating changes in pressure expand and compress the thorax, so that air is drawn into the lung and expelled from it. This type of apparatus has been used to keep patients alive for several months after the respiratory center has been damaged by disease (*e.g.*, poliomyelitis).

[1] COUNCIL ON PHYSICAL MEDICINE AND REHABILITATION, *J.A.M.A.*, **150**, 695, 1952.
FIG. 136. Artificial respiration by the "rocking method." The abdominal viscera push the diaphragm into the thorax, and expiration is evoked when the subject is in the position illustrated; when the head is raised, the viscera pull on the diaphragm and cause inspiration. (*After Eve, F. C., J. A. M. A., vol. 124, p. 964, 1944.*)

In the *rocking method*,[1] the patient is placed in the prone position on a trestle that can be tilted so that either the head or the feet are down (Fig. 136). The patient is rocked by alternately tilting his head and feet to an angle of 45°, about ten times per minute. When the feet are down the abdominal viscera pull the diaphragm down and expand the lungs (inspiration). When the head is down the viscera push the diaphragm into the thorax (expiration). If the subject is a small child this method can be applied without the use of the trestle, by simply holding the child and rocking it.

Many manual methods of artificial respiration have been proposed, but until recently it was difficult to judge their efficiency comparatively.

[1] EVE, F. C., *J. A. M. A.*, **124**, 964, 1944.

In order to do so, Gordon and his associates[1] experimented on 26 volunteers who were anesthetized and rendered completely apneustic by an adequate dose of curare. The tidal volume was measured and compared using six methods, changing the position of the subject and the technique employed.
FIG. 137. Back pressure-arm lift method (after Holger-Nielsen). *A*, placing hands for arm lift; *B*, arm lift; *C*, placing hands for back pressure; *D*, back pressure. (*Gordon, A S., et al., J. A. M. A., vol. 147, p. 1444, 1951.*)

A manual method of artificial respiration should be simple, so that it can be easily learned by anybody. It should not tire the operator, so that it can be kept up for a long time. Methods in which the operator provokes both respiratory movements are superior to those in which only inspiration or expiration is produced. Schäfer's prone pressure method is purely expiratory; the thorax is compressed to expel air, and inspiration is due to the subsequent elastic expansion of the thorax. In Gordon's experiment, it was not found satisfactory; the mean tidal volume was only 485 cc., and in some of the subiects cyanosis could not be abolished.

The method recommended by the Council on Physical Medicine and Rehabilitation of the American Medical Association[1] is the so-called "back pressure-arm lift method" (Fig. 137).

"The subject is placed prone, elbows bent, arms overhead with one hand upon the other. The cheek is placed on the hand, the face turned slightly to one side. The operator kneels on one knee at the head of the subject and puts the foot of the opposite leg near the elbow. He places his hands on the subject's back, in such a way that the thumbs just touch, the heels of the hands being just below a line running between the armpits. He rocks slowly forward, elbows straight, until his arms are approximately vertical, exerting steady pressure upon the chest. Then he commences to rock backward slowly and slides his hands to the subject's arms just above the elbows. He raises the arms until resistance and tension are felt at the subject's shoulders. Then he drops the arms. This completes a full cycle. The cycles are repeated 12 times per minute, the expansion and compression phases being of equal length, the release periods being of minimum duration." Both respiratory movements are thus actively produced. The mean tidal volume was found to be over 1,000 cc. The prone position of the subject has the advantage that if the tongue has lost its tonus it does not fall back obstructing the upper respiratory path. Moreover, if the patient vomits, it will be less likely that foreign bodies are drawn into the trachea.

Resuscitation often requires not only artificial respiration but also the administration of oxygen and CO_2. Circulatory conditions should be taken care of, especially in circulatory collapse, and the body temperature should be maintained.

CHAPTER 27

Exchange of Gases in the Lung

THE EXCHANGE OF gases through the alveolar wall between the air and blood is known as hematosis. The total surface of the alveoli has been calculated to be between 80 and 100 sq. m. in man. Their walls are sufficiently thin and permeable to allow of a rapid interchange of gases. In mammals the interchange of gases takes place between a gaseous environment and a liquid *milieu intérieur*. The fundamental laws of gases must therefore be known in order to understand the phenomena of hematosis.

THE GAS LAWS

The laws governing the gases taking part in hematosis are the laws common to all gases; they apply not only to oxygen and carbon dioxide, but also to inert gases (nitrogen, hydrogen, etc.), toxic gases and vapors (carbon monoxide, hydrocyanic acid, hydrogen sulfide, benzene vapor, etc.), and those used in therapeutics (anesthetics, amyl nitrite, etc.). Through the alveolar walls, water is eliminated in the form of aqueous vapor in the expired air. Heat is also lost through the respiratory surface. Solid particles (silica, coal dust, etc.) are absorbed through the surface.

The principal laws governing the interchange and transport in solution of gases will be briefly summarized here; further details will be found in textbooks on physics.

The Boyle-Mariotte law. Experiments performed by Boyle and Mariotte showed that when the temperature remains constant the pressure of a gas varies inversely with its volume, or conversely the volume varies inversely with the pressure. If p_1 and p_2 are the pressures corresponding to volumes v_1 and v_2,

$$\frac{p_1}{p_2} = \frac{v_2}{v_1}$$

therefore $\quad p_1v_1 = p_2v_2$

whence $\quad p_nv_n = K$

The Boyle-Mariotte law can be stated as follows: at a constant temperature the product of the pressure and volume of a gas has a constant value.

The law of Gay-Lussac (or of Charles). The second fundamental law of gases, discovered by Gay-Lussac, refers to the influence of temperature. At a constant pressure the volume of a gas increases with the temperature. For each rise in temperature of 1°C. the gas expands $1/273$ of its volume at 0°C. This fraction $1/273$ is equal to 0.003663, which is known as the dilatation coefficient of gases. Gay-Lussac's law can be expressed as follows:

$$\frac{V_1}{V_2} = \frac{T_1}{T_2}$$

the volume of gas being directly proportionate to absolute temperature.

If the volume is maintained constant when the gas is heated, the pressure rises $1/273$ of the pressure at 0°C. for each degree centigrade that the temperature is raised; this is known as the pressure coefficient of gases. In this law the interdependence of pressure and volume is again evident, since the volume and pressure coefficients of gases are the same.

Practical applications. The dilatation coefficient of gases is much greater than that of solids and liquids. On the other hand a gas also has great compressibility. For example, at a constant pressure (*e.g.*, 760 mm. Hg) 1 liter of air at 0°C. dilates to 1,073 cc. at 20°C., an increase of 7.3 per cent above the initial volume. These differences are not of great importance when measuring gases with only a rough approximation, as when the vital capacity is measured in a spirometer; but when exact measurements must

be taken (*e.g.*, when the alkaline reserve is measured in volumes of CO^2 per cent, or when the oxygen content of blood is determined) the exact temperature and pressure at which the volume has been measured must be known. Without these data the volume of a gas has no precise significance. To avoid confusion in the exact measurement of a gas, the volume is given

as if it were made at 0°C. and at 760 mm. Hg pressure. The volume read is multiplied by $(273/273 + t) \times (P/760)$, t being the temperature in degrees centigrade and P the barometric pressure in millimeters of mercury.

Pressure measurements and units. The air surrounding the earth is subject to the force of gravity and at sea level exerts a pressure equal to that of a column of mercury 760 mm. high. This is known as a pressure of 1 atmosphere and is approximately equal to 1 kg. per sq. cm. (14.7 lb. per sq. in.). A column of mercury of 1 sq. cm. cross section and 76 cm. height is made up of 76 cc. of mercury, which weighs $76 \times 13.5951 = 1{,}033.2$ gm. (13.5951 is the specific gravity of mercury). This column exerts on its base of 1 sq. cm. a pressure of 1,033.2 gm., and is equivalent to the pressure exerted by the atmosphere on each square centimeter at sea level. When, therefore, it is said that a pressure of 1 atmosphere is equivalent to 1 kg. per sq. cm., an error of 3 per cent is committed, but this error is of no importance in the usual measurements.

A pressure of 1 atmosphere is also equivalent to that of a column of water of 10.33 m. height. Therefore the pressure to which a diver is submitted increases by 1 atmosphere for approximately every 10 m. depth.
FIG. 138. Barometric pressure at different heights above sea level. Small differences due to changes in temperature are not taken into account in the diagram.

Atmospheric pressure. When a person ascends in an airplane or goes up a mountain, the column of air above him decreases as he rises, and the pressure also decreases (Table 23, Fig. 138).

Solubility of a gas in a liquid. If a gas and a liquid are placed in a closed flask, the gas dissolves in the liquid until an equilibrium is reached. If the gas does not combine with the liquid but is simply dissolved in it, the amount of gas absorbed by the liquid depends on (*a*) the nature of the gas and the liquid; (*b*) the temperature; (*c*) the partial pressure of the gas.

The volume of a given gas absorbed by a liquid at a given temperature is constant whatever the pressure. For example, a liquid is placed in a dish within a cylinder closed by a piston (Fig. 139); it dissolves 2 cc. of gas when the piston is in position *A*. The volume of gas in the cylinder is then reduced to one-half by placing the piston in position *B*, and time is allowed for an equilibrium to be established between the gas and the liquid. The amount of gas absorbed is still 2 cc., but at twice the pressure. Therefore at normal temperature and pressure (NTP), *i.e.*, at 0°C. and 760 mm. of mercury, the gas dissolved by the liquid when the piston is in position *B* will have twice the volume of the gas absorbed when the piston is in position *A*.

When the temperature is maintained constant, the amount of gas dissolved by a liquid is direct function

of pressure; in a system of cartesian coordinates this is represented by a straight line (Fig. 145, solution of CO_2). Henry's law of solution of gases states that, if the temperature is maintained constant, the volume of gas, measured at 0°C. and 760 mm. Hg, in solution in a liquid is proportional to the pressure of the gas.
FIG. 139. Diagram of apparatus for demonstrating the effect of pressure on the solution of gases in liquids. When the piston is in position *B*, twice as great a volume of gas is dissolved by the liquid as is dissolved when the piston is in position *A*.

The absorption or solution coefficient is the volume of gas (corrected for NTP) absorbed by 1 cc. of the liquid at a pressure of 760 mm. Hg. The absorption coefficient diminishes as the temperature increases. Substances in solution in a liquid diminish its capacity to dissolve gases.

Dalton's law of partial pressure. In gas mixtures the pressure exerted by each gas depends on the percentage of the gas in the mixture. The pressure exerted by each gas in the mixture is known as the partial pressure of the gas. For example, in a gas mixture of 20 per cent oxygen and 80 per cent nitrogen at a pressure of 760 mm. Hg, the partial pressure of oxygen is $(760 \times 20)/100 = 152$ mm. Hg, and that of nitrogen $(760 \times 80)/100 = 608$ mm. Hg. The sum of the partial pressures is the total pressure, *i.e.*, $152 + 608 = 760$ mm. Hg. Therefore

$$\text{Partial pressure} = \frac{\text{Total pressure} \times \text{Percentage concentration of gas}}{100}$$

For example, if the concentration of CO_2 in alveolar air is 5.5 per cent, and the atmospheric (total) pressure is 760, the partial pressure of CO_2 is $(760 \times 5.5)/100 = 41.8$ mm. Hg.

When calculating the partial pressure of a gas, all the gases in the mixture must be taken into account, including the tension of water vapor. This is particularly important when calculating the partial pressure of gases in alveolar air, which is saturated with water; water vapor at 37°C. has a tension (partial pressure) of 47 mm. Hg. (Table 24). For example, when calculating the partial pressure of CO_2 and O_2 in a sample of alveolar air which has 5.3 per cent CO_2 and 14 per cent O_2, the barometric pressure being 756, first the tension of water vapor (47 mm. Hg at 37°C.) must be subtracted from the total pressure: $756 - 47 = 709$. The partial pressure of CO_2 is 5.3 per cent of 709, *i.e.*, 37.6 mm. Hg, and that of O_2 is 14 per cent of 709, *i.e.*, 99.3 mm. Hg.

Table 24. Tension of Water Vapor at Different Temperatures

Temperature, °C.	*Tension of Water Vapor, Mm. Hg*
0	4.6
10	9.2
20	17.5
30	31.8
37	47.0
40	55.3
50	92.5

An understanding of partial pressure is important when a mixture of gases is in contact with a liquid, because each gas goes into solution independently of the others, in an amount directly proportional to its own partial pressure (Dalton's law). The fixation of oxygen by hemoglobin is also dependent on the oxygen partial pressure. It is therefore important to know fairly accurately the minimum partial pressures of oxygen compatible with the normal functioning of the tissues. Recent developments in aviation, pathology, etc., have enhanced the value of this knowledge.

Equilibrium between a liquid and a gas. If a certain amount of liquid is placed in a closed flask (Fig. 149) and the flask is then filled with a gas mixture of known composition, an interchange of molecules between the liquid and the gas will commence and, according to Henry's and Dalton's laws, will continue until an equilibrium is established. Once the equilibrium is established the amount of

gas in solution remains constant, because for each molecule of gas that goes into solution, another is set free. The gases are at the same tension in the liquid as in the gas. The tension of a gas in a liquid is determined by the method known as tonometry. The time taken for the establishment of this equilibrium depends on the area of the surface of contact in relation to the volume of liquid. To increase the surface of contact, the flask is placed horizontally and rotated.

Combination of gases with liquids. Henry's law is valid only when a gas goes into solution in a liquid; if there is chemical affinity between the gas and the liquid, or a substance dissolved in the liquid, either of two possibilities may occur:

1. Chemical combination may not be dependent on the partial pressure of the gas; *e.g.*, CO_2 in contact with a solution of Na(OH) is absorbed whatever the partial pressure as long as there is Na(OH) in solution.
2. Chemical combination may be dependent on partial pressure The amount of gas fixed by the solution or dissolved substance then decreases if its partial pressure is lowered, and vice versa, but not necessarily in direct proportion; *i.e.*, Henry's law is not applicable. The gas combined is set free in a vacuum. The combination of oxygen with hemoglobin corresponds to this second type.

Diffusion. Subs ances in solution migrate from the more to the less concentrated parts of the solvent. In the same way gases diffuse from where the partial pressure is higher toward where it is lower, at a speed that increases with the difference in pressure.

Krogh's diffusion constant is the volume of a gas (in cubic centimeters) that passes through the pulmonary membranes in 1 min., when the difference in the partial pressure of the gas in the alveolar air and the blood in the pulmonary capillaries is 1 mm. Hg. The oxygen diffusion constant varies from a minimum of 20 in the resting condition to a maximum of 60 in exercise.

METHODS OF GAS ANALYSIS

The methods used in the study of the respiratory function of the blood (gas transport) and hematosis are of interest in physiology, applied physiology (*e.g.*, aviation physiology), and pathology. Only the more current methods will be briefly considered; further details can be obtained in technical manuals.

Determination of CO_2 and O_2 in air. One of the modifications of Haldane's buret is most commonly used for this purpose. A sample of air is collected and its volume accurately measured. The air is then washed in a flask containing KOH, which fixes CO_2. The volume of air is again measured; the difference found corresponds to the CO_2. Oxygen is then fixed by an alkaline solution of pyrogalate and the volume is again measured; the difference corresponds to the O_2. The remainder consists of inert gases: nitrogen, helium, argon, etc. Other gases (CO, anesthetic gases, etc.) can be measured in this apparatus appropriately modified. The CO_2 and O_2 content of the atmosphere, expired air, alveolar air, etc., can be determined by this method. Alveolar air is collected by making a forced expiration into a long tube and then closing it with the tip of the tongue. A lateral tube placed near the extremity close to the mouth is connected with a sampling bulb into which a sample of the last air expired is drawn.

Determination of the gases in the blood. Van Slyke and Neill's[1] apparatus is commonly used for this purpose. A sample of liquid is taken and the gases it contains are set free by simple vacuum evacuation or by means of chemical substances; the volume is measured by an indirect method and corrected for NTP. The percentage of the gas in the mixture is determined by this procedure, but not its partial pressure; to obtain the latter a tonometric method must be used.

Tonometry. To determine the partial pressure of a gas in blood (*e.g.*, oxygen in renal venous blood), a sample is taken by puncturing the vein and collecting the blood under mineral oil in a tube containing an anticoagulant agent. The content of oxygen of a given volume is measured; let us suppose a concentration of 12 per cent is found. Small amounts of this blood are then distributed in a series of flasks (Fig. 149), which are then filled with mixtures of gases with varying oxygen concentration (10, 11, 12 per cent, etc.). The flasks are closed and gently rotated until a gaseous equilibrium is established. The oxygen content of the blood in each flask is then determined. It will be found to be below 12 per cent in some and above 12 per cent in others, but in one of the flasks it will remain constant at 12 per cent. The blood taken from the vein therefore was in gaseous equilibrium with the gas in that flask (let us suppose it contained 15 per cent oxygen). The barometric pressure and temperature are read, the tension of water vapor is subtracted, and the oxygen partial pressure of the gas mixture is calculated. This oxygen partial pressure is the same as that of the blood sample

[1] VAN SLYKE, D. D., *et al.*, *J. Biol. Chem.*, **61**, 523, 1924.

fishes, in which the air has a high O_2 concentration. The O_2 partial pressure in the swim bladder is much higher than in the tissues; therefore it cannot have accumulated there by simple diffusion, but must have been actively secreted. The epithelial lining of the swim bladder has a glandular aspect and is controlled by the nervous system, conditions that are not similar to those of the alveoli. The function of the swim bladder differs considerably from that of the lungs, and it is not justifiable to apply facts observed in the former to events occurring in the latter.

Physical laws alone are sufficient to explain the process of diffusion of gases through the alveolar capillary membrane. Experiments by Hartridge and Barcroft have shown that the O_2 partial pressure in the alveolar air is always slightly above that in the blood. It has also been calculated that 250 cc. per min. of O_2 can diffuse through the alveolar membrane for every millimeter of difference in the O_2 partial pressures on each side of the membrane.

Normally the difference in O_2 partial pressure between the alveolar air and venous blood is approximately 60 mm. Hg and the oxygen consumption at rest is 300 cc. per min. The oxygen consumption can rise to 4,000 cc. per min. in maximum muscular effort. In a normal individual, therefore, the absorption of O_2 is not limited by its capacity to diffuse through the lungs but by other factors, *i.e.*, pulmonary ventilation (the speed at which the alveolar air is renewed) and the circulatory factor (the speed at which the erythrocytes circulate through the lung capillaries). The oxygen capacity of hemoglobin is constant; approximately 95 per cent is saturated at the O_2 partial pressure that exists at sea level. At high altitude another factor comes into play which limits oxygen absorption, *i.e.*, the decrease in O_2 partial pressure (see "Anoxia," Chap. 33).

When the organism is producing a maximum muscular effort the factor that limits oxygen absorption is the maximum amount of blood that can circulate through the lungs in unit time.

CO_2 has a speed of diffusion approximately 25 times that of O_2. It has been calculated that a difference in CO_2 tension of 0.03 mm. Hg between the blood and alveolar air would be enough to assure the elimination by simple diffusion of all the CO_2 produced by a normal person at rest. In the elimination of CO_2 an important part is played by carbonic anhydrase (see Chap. 30).

In the interchange of gases in the lung, the thickness of the membrane (alveolar and capillary) that separates the blood and the alveolar air is also important in pathologic conditions but not in normal ones. The presence of secretions or frothy edematous fluid in the alveoli, or of edematous thickening of the membrane, represents an obstacle to the diffusion of O_2. The elimination of CO_2 is not hindered so much because of its greater diffusion velocity.

Absorption of gases from closed cavities. The air in a closed cavity within the organism is gradually absorbed. Thus, when a bronchus is obstructed the air in the corresponding part of the lung is reabsorbed and atelectasis follows. The air in a pneumothorax is also reabsorbed. The mechanism by which air is reabsorbed is as follows:[1] The sum of the partial pressures of gases in arterial blood is the same as the atmospheric pressure, but in venous blood it is 54 mm. Hg less, because the considerable decrease in O_2 partial pressure caused by the absorption of O_2 by the tissues is not counterbalanced by the slight increase in CO_2 partial pressure (see Table 25). This causes the gases in a closed cavity to diffuse out into the surrounding tissues according to their velocity of diffusion and the capacity of the blood to dissolve them. After a few days the air in the cavity is stabilized and has the same O_2 and CO_2 content as the tissues. Reabsorption of the gaseous mixture is delayed by the presence of N_2, which is less soluble than O_2 and CO_2. The cavity is adjusted to atmospheric pressure and is gradually reduced until it disappears.

CHAPTER 28

The Transportation of Oxygen by the Blood

OXYGEN TENSION IN the alveolar air is approximately 100 mm. Hg; at this tension arterial blood contains 19 volumes per cent of oxygen. The solubility coefficient of oxygen in blood at a pressure of 760 mm. Hg and at 38°C. is 0.022; at 100 mm. and at the same temperature, blood can carry only 0.3 volumes per cent oxygen in solution. The greater part of the oxygen in the blood is in unstable combination with hemoglobin.

The molecular weight of hemoglobin has been found to be between 63,000 and 66,400 (see Chemical properties of hemoglobin, Chap. 4) and each molecule has four atoms of iron. To simplify calculations it is usual to divide the molecular weight by four, so that 16,400 gm. hemoglobin corresponds to 1 gram atom of iron (56 gm.). This amount of hemoglobin combines with 1 gram molecule of oxygen at 760 mm. Hg and at 0°C, *i.e.*, with 22.41 liters. One gram of hemoglobin, therefore, combines with 1.34 cc. O_2, a fact that has been established repeatedly by experimental determination. Normal blood has approximately 15 gm. per cent hemoglobin, and this would hold

$$1.34 \times 15 = 20.1 \text{ cc. } O_2$$

if the hemoglobin were completely saturated. At an O_2 tension of 100 mm. Hg, hemoglobin is only 95 per cent saturated; therefore arterial blood with a hemoglobin content of 15 gm. per cent holds 19.1 cc. O_2. Thus it is possible to calculate the hemoglobin concentration in blood by determining its O_2 content at a given O_2 tension, or vice versa the oxygen content if the hemoglobin concentration and the O_2 tension are known.

Hemoglobin enters into chemical combination with O_2, since both substances are in definite and constant stoichiometric proportions, and the formation heat of HbO_2 is also constant.

The combination of Hb and O_2 is reversible, *i.e.* $Hb + O_2 \leftrightarrows HbO_2$. The direction in which it takes place depends on the following factors: oxygen partial pressure, temperature, pH, and the electrolytes in the solution. This unstable combination is usually known as "oxygenation" and not "oxidation" of hemoglobin.

Oxygen dissociation curve of hemoglobin. Conditions governing the fixation of oxygen by hemoglobin have been determined experimentally. In order to do this a few cubic centimeters of pure hemoglobin solution at a known concentration are placed in appropriate containers. The containers are then filled with gas mixtures of O_2 and N_2, varying the oxygen partial pressure by 10 mm. Hg from 0 to 100 mm. Hg. The blood is brought into gaseous equilibrium with the gas mixture, and the amount of oxygen absorbed by the blood at different O_2 tensions is determined, establishing the percentage of O_2 saturation, *i.e.*, the proportion of O_2 absorbed in relation to maximum absorption (1.34 cc. O_2 per gm. hemoglobin). The data obtained are plotted on *x-y* coordinates. The resulting curve is a hyperbole and is known as the "oxygen dissociation curve of hemoglobin, as a function of O_2 partial pressure" (Fig. 141).

If the experiment is repeated with blood instead of a solution of pure hemoglobin, a curve of different shape is obtained. At one time it was

thought that crystallized hemoglobin differed from hemoglobin in blood, but later it was established that the difference in the dissociation curves was due to the electrolytes in the blood.

The principal factors that modify the O_2 dissociation curve of hemoglobin are (*a*) temperature; (*b*) electrolytes; (*c*) hydrogen ion concentration (pH).
FIG. 141. Dissociation curve of hemoglobin at different oxygen pressures. The curve corresponding to a solution of pure hemoglobin is a regular hyperbole. Those corresponding to blood are irregular because of the electrolytes in solution. Presence of CO_2 shifts the dissociation curve to the right; the curve of normal blood is that corresponding to a CO_2 partial pressure of 40 mm. Hg.

An increase in temperature diminishes the capacity of O_2 fixation, *i.e.*, favors the dissociation of HbO_2. During tissue activity (*e.g.*, muscular contraction) there is a local rise in temperature. This favors release of O_2 from hemoglobin and its delivery to the tissues, in circumstances in which the need of O_2 increases.

Electrolytes, *i.e.*, the different ions in the blood plasma and erythrocytes, modify the O_2 dissociation curve of hemoglobin. The effect varies with the ion and its concentration. Pure hemoglobins prepared from blood of different mammalian species have approximately equal oxygen capacity, but the O_2 dissociation curve of the whole blood varies from one species to another. This is due to the electrolytes in the blood, as is shown by the fact that, although the O_2 dissociation curves of human and dog's blood are not the same, nevertheless a solution of pure human hemoglobin has an O_2 dissociation curve similar to that of dog's blood if electrolytes are added to the solution in the same concentration as they are found in dog's blood.

An increase in hydrogen ion concentration diminishes the oxygen fixation capacity of the blood, and a decrease increases the O_2 capacity (Fig. 141). Thus CO_2 entering into the capillaries from the tissues acidifies the blood and releases oxygen from hemoglobin, while in the lungs the loss of CO_2 into the alveolar air diminishes the acidity of the blood and increases its oxygen fixation capacity. Other conditions in which hydrogen ion concentration is of importance will be considered in Chap. 33.

The interaction of the different factors results in release or fixation of O_2 by hemoglobin according to the needs of the organism. Several examples of interdependent equilibriums will be given when dealing with the transportation of CO_2 by the blood.

Passage of oxygen into the tissues. Gases in arterial blood remain without change until the blood arrives at the capillaries. The thin capillary walls are in direct contact with the tissue cells or fluids. The oxygen partial pressure in the tissues is low (30 mm. Hg or less). Oxygen therefore diffuses from the erythrocytes to the plasma, and through the capillary wall into the tissue fluids and the cells, owing to the descending gradient in partial pressure. Moreover, dissociation of oxygen from hemoglobin is facilitated by the increase in acidity (CO_2 and sometimes lactic acid) and, when there is great activity, by an increase in local temperature. The amount of oxygen that blood releases to the tissues is conditioned by the activity of the tissues and the velocity of the circulation.

Oxygen reserve. The average oxygen saturation of arterial blood is 95 per cent. The breathing of pure oxygen has little effect on this percentage. Arterial blood holds 19 volumes per cent O_2, and venous blood holds 14 volumes per cent. The total blood volume in a normal adult is approximately 5 liters; if half of this is arterial blood and the other half is venous, the total amount of O_2 in the blood is 850 cc. To this must be added a small quantity of O_2 dissolved in the tissues, and the O_2 in alveolar air, to obtain the total O_2 in the body. Oxygen consumption at rest is approximately 300 cc. per min., and considerably more during exercise. Therefore if the gaseous interchange in the lungs

is stopped, there is scarcely enough O_2 in the body to supply its needs during 3 min. when resting, and an even shorter time when working. A few minutes after the gaseous interchange in the lungs has been stopped, therefore, symptoms of asphyxia appear. Anoxia (lack of oxygen) causes severe and even fatal disturbances if the respiratory interchange is not renewed without delay. Mammals, including man, have no oxygen reserve, but poikilothermic animals can live for some time without taking in oxygen, because they have a much lower rate of oxygen consumption.

CHAPTER 29

Physicochemical Equilibriums in the Blood and Tissues

THE EXISTENCE IN the blood of many interdependent equilibriums has been well established. For instance, a change in CO_2 concentration modifies the pH, alkali reserve, Hb-HbO_2 ratio, cell Cl–plasma Cl ratio, etc. The transportation of gases is closely dependent on these important physiologic equilibriums. To have a clear idea of their significance certain fundamental physicochemical concepts, such as hydrogen ion concentration (pH), buffer systems, etc., must be well understood.

Concentration. The concentration of a substance is usually given by the weight or volume of the substance contained in the total volume in which it is diluted. Thus a 10 per cent solution of glucose is one that contains 10 gm. glucose in 100 cc. of the solution. In certain cases this way of expressing concentration is quite clear, *e.g.*, 0.9 per cent NaCl, or 2 per cent $CuSO_2$ need no further explanation. In other cases further data must be given to avoid confusion; thus a 40 per cent solution of alcohol may contain 40 cc. alcohol in 100 cc. of solution (volume to volume ratio, V/V), or 40 gm. alcohol in 100 cc. of solution (weight to volume ratio, W/V).

The physicochemical concept of concentration is somewhat different, and it is always given in gram molecules (or gram atoms, or gram ions) in unit volume of 1 liter. Physicochemical concentration is usually expressed by the letter c preceding the chemical symbol for the substance, or by including the symbol in brackets; thus cCa, or [Ca] signifies calcium concentration. For example, the molecular weight of glucose is 180 gm.;[1] therefore a solution containing 180 gm. per liter (W/V) in physical chemistry is expressed thus: [glucose] = 1 or 1 mole, because this solution contains 1 gram molecule per liter. A solution containing 1.8 gm. of glucose per liter (*i.e.*, $\frac{1}{100}$ gram molecule) is expressed as [glucose] = 0.01 or 0.01 mole, etc.

The atomic weight of Na is 23 and that of Cl is 35.5; therefore the molecular weight of NaCl is 58.5. A solution containing 5.85 gm. of NaCl ($\frac{1}{10}$ gram molecule) in 1 liter is expressed as [NaCl] = 0.1. This solution contains 0.1 gram atom of Na and 0.1 gram atom of Cl; therefore the concentrations of these atoms are expressed as [Na] = 0.1 and [Cl] = 0.1. If 90 per cent of the NaCl is dissociated into its constituent ions Na^+ and Cl^-, the concentration of Cl^- ion will be 90 per cent of 0.1, *i.e.* 0.09, when dealing with physicochemical concepts, and it will be expressed as $[Cl^-] = 0.09$. In weight of Cl this means there is $35.5 \times 0.09 = 3.195$ gm. of Cl^- ion per liter of solution.

This apparently more complicated way of expressing concentrations has many advantages and is really simpler in certain cases; the student will therefore find it useful to become familiar with this terminology. Thus two substances that are in the same concentration, in physicochemical parlance, have an equal number of molecules, or atoms, or ions in solution. For example, by chemical analysis it has been found that normal human blood contains, on an average, 250 mg. per cent of Cl and 160 mg. per cent of Na. These figures do not tell immediately what is the ratio of Na to Cl in blood, but they

[1] It is exactly 180.0936, because the atomic weight of H is not 1, but 1.0078. Where greater accuracy is not needed, molecular weights are usually given with only the first decimal.

can be converted to moles or millimoles (one thousandth part of a mole). One mole of Na weighs 23 gm. and one millimole 23 mg.; therefore 160 mg. Na per cent equals 6.96 millimoles per cent or 69.6 millimoles per liter (0.0696 mole). In the same way, 250 mg. per cent Cl equals 70.4 millimoles per cent and 0.0704 mole per liter. The concentration of Na and Cl in blood is expressed in physicochemical terminology as: [Na] = 0.0696 and [Cl] = 0.0704, and immediately it will be seen that total blood contains more atoms of Cl than of Na.

Another example will emphasize the advantage of using the physicochemical way of expressing concentration. The molecular weight of hemoglobin is 16,400 gm. per atom of iron. One mole of hemoglobin fixes one mole of molecular oxygen (O_2), *i.e.*, 22.41 liters. Therefore blood containing 16.4 gm. per cent of hemoglobin has 1 millimole per cent of hemoglobin, which can take up 1 millimole of O_2, *i.e.*, 22.41 cc. of oxygen for every 100 cc.

When the concepts of pH and buffer systems are dealt with, it will be seen how important it is to be familiar with this terminology.

Degree of dissociation. An electrolyte dissolved in water is dissociated into positive (+) ions, or cations, and negative (−) ions, or anions. Dissociation progresses until a dynamic equilibrium is established in which for every molecule dissociated another is formed by the union of the two ions in solution. The ratio of dissociated molecules (n) to total molecules, *i.e.*, the sum of dissociated (n) plus nondissociated molecules (m) is the degree of dissociation (V):

$$V = \frac{n}{n + m}$$

A solution in which 30 per cent of the molecules are dissociated has a degree of dissociation equal to 0.3:

$$V = \frac{30}{30 + 70} = 0.3$$

The degree of dissociation increases with dilution and with rise in temperature; its greatest possible value is 1. The degree of dissociation should not be mistaken for the dissociation constant.

Dissociation constant. Mathematical analysis and experimental determination[1] have proved that the ratio of the product of the concentrations of the dissociated ions to the concentration of the nondissociated molecules is constant:

$$K = \frac{[A^-][C^+]}{[AC]}$$

in which K is the dissociation constant, $[A^-]$ the concentration of anions, $[C^+]$ the concentration of cations, and [AC] the concentration of nondissociated molecules. Each electrolyte has its own dissociation constant, which varies only with the temperature and remains unaltered at all concentrations.

The dissociation constant has particular significance in acids and alkalis, because their "strength," *i.e.*, acidity or alkalinity, depends on it.

Acids dissociate into H^+ and the A^- corresponding to the particular acid. The dissociation constant of acids is expressed as follows:

$$K = \frac{[A^-][H^+]}{[AH]}$$

"Strong" acids (*e.g.*, HCl, H_2SO_4, HNO_3, etc.) have a high dissociation constant; therefore there are many H^+ in solution. "Weak" acids (*e.g.*, carbonic acid, acid phosphate, acetic acid, etc.) have a low dissociation constant and relatively few H^+ in solution.

Alkalis dissociate into hydroxyl ion (OH^-) and a cation; "strong" alkalis (*e.g.*, KOH, NaOH) have a high, and "weak" alkalis a low, dissociation constant.

Dissociation constant of water. Several experimental procedures have proved that pure water also dissociates into its constituent ions:

$$H_2O \rightleftarrows H^+ + OH^-$$
There are not many dissociated molecules; at 22°C. there are 18 gm. (1 mole) of water dissociated for every 10,000,000 liters. Therefore at 22°C. in every 10,000,000 liters of water there is 1 gram atom (*i.e.*, 1 gm.) H^+ and 1 gram atom (*i.e.*, 17 gm.) OH^-. In 1 liter of water there is 10^{-7} gram atom of H^+ and 10^{-7} gram atom of OH^-.

The dissociation constant of water is expressed as follows:

$$K = \frac{[H^+][OH^-]}{[H_2O]}$$

[1] Further details will be found in textbooks on physical chemistry or biophysics.

The concentration of nondissociated molecules is so high, compared to the concentration of dissociated molecules, and varies so little when the factors in the numerator change, that it can be considered constant without com-
FIG. 142. Diagram illustrating total, potential, and real acidity. The weak acid has the same total acidity (titrated against a base) as the strong acid. The strong acid is highly dissociated and has a high real acidity. The weak acid is less highly dissociated and its real acidity is low. Potential acidity corresponds to the non-dissociated acid.

mitting any considerable error. Therefore

$$K = \frac{[H^+][OH^-]}{k}$$

where k is the concentration of nondissociated molecules. From this $K \times k = [H^+][OH^-]$, but the product of two constants is also a constant: $K \times k = Kw$, therefore the dissociation constant of water can be expressed as

$$Kw = [H^+][OH^-]$$

At 22°C. it is $10^{-7} \times 10^{-7}$ or 10^{-14}, *i.e.*, $Kw = 0.000\,000\,000\,000\,01$. The value of this constant varies with the temperature, since the degree of dissociation increases with the temperature, but it is usual when making calculations to refer to the dissociation constant at 22°C., *i.e.*, when $Kw = 10^{-14}$.

The dissociation constant of water has considerable significance. Neutral water is not water that does not contain H^+ and OH^-, but water in which there is the same concentration of both these ions. If NaCl is dissolved in water, most of it is dissociated into Na^+ and Cl^-, but the concentration of H^+ and OH^- does not vary, therefore the solution remains neutral.

If an acid or a base is added to neutral water a different process takes place. An acid is, by definition, a substance which releases H^+ when in solution. For example, if HCl is added to neutral water, the acid dissociates into H^+ and Cl^-, but the dissociation constant of the water remains unchanged. Let us suppose that HCl was added in sufficient quantity to give a H^+ concentration of 0.01 (*i.e.*, 10^{-2}); automatically the OH^- concentration shifts to 10^{-12} and $[H^+][OH^-] = 10^{-2} \times 10^{-12} = 10^{-14}$. If an alkali is added, *e.g.*, NaOH, in a quantity such that the concentration of OH^- is 0.1 (*i.e.*, 10^{-1}), the concentration of H^+ automatically shifts to 10^{-13}.

Therefore when the cH^+ is known the cOH^- is also known and acidity or alkalinity can be expressed in the concentration of either ion. It is usual to express it in the cH^+. Solutions in which $cH^+ = 10^{-7}$ are neutral. If this value increases, the solutions are acid; if it decreases, they are alkaline.

Real, potential, and total acidity. Equal volumes (*e.g.*, 10 cc.) of 0.1 *N* HCl and 0.1 *N* acetic acid have the same acidity when titrated with an alkali. Thus both require 10 cc. 0.1 *N* NaOH to be completely converted into NaCl and sodium acetate respectively. This acidity determined by volumetric titration is known as total acidity.

There is, however, a certain difference between the solutions of these acids; HCl is a "strong" acid, highly dissociated, and acetic acid is a "weak" acid, much less dissociated. A 0.1 *N* solution of HCl is 84 per cent dissociated; acetic acid in 0.1 *N* solution is only 1.36 per cent dissociated. The value of this real acidity, which varies for each acid, is given by the H^+ concentration. Figure 142 illustrates diagrammatically the acidity of strong and weak acids. Total acidity is the same for both acids, but real acidity is greater in the strong acids.

Potential acidity corresponds to the nondissociated fraction of the acid. When base is added the nondissociated molecules are progressively dissociated until the acid is completely neutralized.

The determination of real acidity (expressed

as cH^+) has great biological importance. For example, the intensity of the acid taste of a solution is due to its cH^+; sucrose in solution boiled in the presence of an acid is split (hydrolyzed) into fructose and glucose; the velocity of this reaction is proportional to the cH^+. Many other instances could be given in which the physiologic or toxic effects of an acid are due to the cH^+.

The pH nomenclature. To understand clearly the significance of the pH notation of cH^+ it is necessary to recall certain mathematical rules referring to logarithms.

The cH^+ of organic fluids and of alkaline solutions is extremely low; thus the cH^+ of water is 0.000 000 1, and that of 0.1 *N* NaOH is in the twelfth figure after the decimal point. The writing of these figures is cumbersome, and it is easy to make mistakes in reading them. Fortunately there are other, simpler ways of expressing them. The figures 100 and 1,000 can be written as 10^2 and 10^3 respectively. The exponents of 10 are the logarithms of the number represented; 2 is the logarithm of 100 and 3 the logarithm of 1,000. Two figures can be multiplied by adding their logarithms; the sum is the logarithm of the product. Thus

$$100 \times 1{,}000 = 10^2 \times 10^3 = 10^{2+3} = 10^5 = 100{,}000$$
$$\log 100 + \log 1{,}000 = \log 100{,}000$$

To divide one figure by another their logarithms are subtracted:

$$10{,}000 \div 100 = 100$$
$$10^4 \div 10^2 = 10^{4-2} = 10^2$$
$$\log 10{,}000 - \log 100 = \log 100$$

The log of 1 is 0, as is shown by the following calculation:

$$100 \div 100 = 1$$
$$100 \div 100 = 10^2 \div 10^2 = 10^{2-2} = 10^0$$
therefore $1 = 10^0$ and $\log 1 = 0$

The logarithms of figures in geometric progression are in arithmetic progression:

$\log 100 = 2$ or $100 = 10^2$
$\log 10 = 1$ or $10 = 10^1$
$\log 1 = 0$ or $1 = 10^0$
$\log 0.1 = -1$ or $0.1 = 10^{-1}$
$\log 0.01 = -2$ or $0.01 = 10^{-2}$
$\log 0.001 = -3$ or $0.001 = 10^{-3}$

Therefore quantities smaller than unity can be easily expressed as negative exponents of 10. This negative exponent will increase as the figures diminish. For example, the cH^+ of neutral water is 0.000 000 1, which can be more easily expressed as 10^{-7}. Not only multiples or submultiples of 10 can be represented in this way, but also other numbers. For example $2{,}300{,}000 = 2.3 \times 1{,}000{,}000 = 2.3 \times 10^6$. The logarithm of 2.3 is 0.36 (the two first decimal figures are sufficient for the accuracy of pH determinations). Therefore

$$2.3 \times 1{,}000{,}000 = 10^{0.36} \times 10^6 = 10^{0.36+6} = 10^{6.36}$$
and $\log 2{,}300{,}000 = 6.36$

Now let us take the case of a figure below unity, *e.g.*, a cH^+ of 0.000 002 3. This can be written in several other ways:

$$0.0000023 = 2.3 \times 0.000001 = 2.3 \times 10^{-6} = 10^{0.36} \times 10^{-6} = 10^{-5.64}$$
Since $0.36 - 6 = -5.64$
therefore $0.0000023 = 10^{-5.64}$

The exponent 5.64, without the negative sign, is the pH[1] corresponding to $cH^+ = 2.3 \times 10^{-6}$. As a general rule $cH^+ = 10^{-pH}$. In equations of this type the exponent of 10 is the log of the figure in the other term of the equation; therefore $-pH = \log cH^+$. Multiplying by -1 we have $pH = -\log cH^+$; also $pH = \log \frac{1}{cH^+}$ because the exponent of 10 changes sign on passing from the numerator to the denominator. Thus if $cH^+ = 0.001$, then $pH = \log \frac{1}{0.001}$, and as $\frac{1}{0.001} = 1{,}000$, $pH = \log 1{,}000 = 3$.

The pH, therefore, is the logarithm of the hydrogen ion concentration without the negative sign, and also the logarithm of the reciprocal of the cH^+.

The cH^+ of a solution is now always expressed by the pH notation introduced by Sörensen. The figure corresponding to the cH^+ is converted into an exponent of 10, and this exponent without the negative sign is the pH. Thus the cH^+ of water at 22°C. is $1 = 10^{-7}$, and the pH is 7.

This is the cH^+ concentration of water at 22°C.; therefore pH 7 is that of neutral water at this temperature. Dissociation increases with temperature, however, and at other temperatures the pH of neutral water is different; *e.g.*, at 18°C., $Kw = 0.64 \times 10^{-14}$. In neutral water, $[H^+] = [OH^-]$; therefore at 18°C. the concentration of both these ions is 0.8×10^{-7}, since $0.8 \times 10^{-7} \times 0.8 \times 10^{-7} = 0.64 \times 10^{-14}$.

[1] The symbol pH is formed by the initial of "power" (exponent) and the symbol for hydrogen.

The cH^+ of neutral water at 18°C. is therefore

$$0.8 \times 10^{-7} = 8 \times 10^{-8} = 10^{0.9} \times 10^{-8} = 10^{-7.1};$$

therefore the pH of neutral water at 18°C. is 7.1.

At body temperature (37°C.) the neutral pH is 6.78. When no mention is made of the temperature, the pH corresponds to that at 22°C., at which the neutral point is pH 7.

It is important to note that as real acidity increases the pH diminishes, because the value of the pH indicates the position of the significant figure after the decimal point. Thus for $cH^+ = 0.001$, $pH = 3$ and for $cH^+ = 0.01$, $pH = 2$, and as the significant figure is nearer to the decimal point the concentration increases. The pH indicates the dilution of H^+; a high pH means a high dilution, and vice versa.

Another result of this way of expressing cH^+ is that for every unit increase in the pH the H^+ are diluted 10 times.

The normal values of the pH of organic fluids are given in Table 26.

Table 26. Normal pH Values in Organic Fluids

Fluid	*pH Value*
Gastric juice	1.0–3.0
Urine	4.8–7.4
Blood	7.3–7.45
Saliva	5.8–8.5
Bile	7.5–8.1
Pancreatic juice	7.3–8.1

Methods for determining pH. There are two methods most commonly used to determine the pH of a solution; one uses indicators, the other a potentiometer. The indicator method uses chemical substances that change color when the cH^+ of the solution changes. The pH at which the change of color takes place is characteristic for each indicator, and a series of these can be used for determining the different pH ranges.

In the potentiometric method a platinum electrode (or a gold electrode plated with platinum) is saturated with hydrogen so that when placed in a fluid it behaves as a hydrogen electrode. When a zinc electrode is submerged in a solution containing zinc ions, a potential is established which is dependent on the zinc ion concentration of the solution; similarly with a hydrogen electrode a potential is established which is dependent on the cH^+ of the solution. This potential is measured with a potentiometer and the pH of the solution is then calculated.

Buffer systems. Salts of a weak acid and a strong base (*e.g.*, sodium acetate) or of a strong acid and a weak base (*e.g.*, ammonium chloride) act as buffers. In the organism only buffers of the former type are found. Sodium acetate can be taken as an example. The $CH_3{\cdot}COO^-$ (acetate ion) will be expressed as $Acet^-$ and the nondissociated acetic acid as Acet H.

Buffer salts do not give a neutral solution as do salts of a strong acid and a strong base. For example, NaCl dissociates into Na^+ and Cl^-, but the H^+ and OH^- in the water of the solution do not vary. Buffer salts are also dissociated to a high degree when in solution, and as there are H^+ and OH^- in the solution, the situation can be represented as

$$\begin{matrix} Acet^- & Na^+ \\ H^+ & OH^- \end{matrix}$$
Reading the columns vertically it is seen there is acetic acid (a weak acid) and NaOH (a strong base). The weak acid is not considerably dissociated, and a high proportion of nondissociated acetic acid (Acet H) is found. The strong base on the other hand is considerably dissociated. Therefore in a solution of sodium acetate the OH^- predominates and the solution is alkaline. Of course, this alkalinity is not considerable and is not equivalent to a solution of NaOH, as might be thought by the example given. These physicochemical reactions are the result of equilibriums that can be calculated according to the mass law for each one of the electrolytes that takes part in them. These calculations will be found in treatises on physical chemistry or biophysics.

A very important buffer found in the organism is sodium bicarbonate, which is dissociated into Na^+ and bicarbonate ion:

$$Na_2HCO_3 \rightleftarrows HCO_3^-Na^+$$
As there are ions in the water of the solution, this can be represented by

$$\begin{pmatrix} HCO_3^- \\ H^+ \end{pmatrix} \quad \begin{matrix} Na^+ \\ OH^- \end{matrix}$$
The column on the left in parentheses represents the weak carbonic acid which is not much dissociated; and the column on the right the strong, highly dissociated base. An aqueous solution of $NaHCO_3$ is alkaline (turns litmus paper blue). This explains the paradoxical fact that an acid salt (sodium acid carbonate) gives an alkaline solution.

Many substances act as buffers in the organism; among the most important are sodium bicarbonate, disodium phosphate, proteins, etc.

A buffer system is obtained by adding the corresponding acid to the buffer, *i.e.*, it is a solution of a weak acid and its salt. An important property of buffers is made evident in buffer systems. For example, in a solution of acetic acid and sodium acetate, the acid dissociates according to its dissociation constant:

$$\frac{[Acet^-][H^+]}{[Acet\ H]} = K$$

whence $$[H^+] = K\frac{[Acet\ H]}{[Acet^-]}$$

Acetic acid is a weak acid; therefore it is not greatly dissociated. If sodium acetate, which has a considerable degree of dissociation, is added, the concentration of acetate ion ($Acet^-$) increases and a new dynamic equilibrium is established in which more of the $Acet^-$ is formed from sodium acetate and less from acetic acid. The dissociation of the acid diminishes and therefore the cH^+ also diminishes.

In this system the dissociation of $Acet^-$ is dependent on the degree of dissociation (δ) of the sodium acetate.

$$Acet^-] = \delta[Na\ Acet]$$

Therefore, substituting ($Acet^-$) in the former equation, we have

$$[H] = K\frac{[Acet\ H]}{\delta[Na\ Acet]}$$

The degree of dissociation varies with the concentration, but as there are no great changes in concentration in organic fluids, δ can be considered as constant. K/δ is therefore also a constant, known as K_1, whence

$$[H^+] = K_1\frac{[Acet\ H]}{[Na\ Acet]}$$

or, in general terms, $$[H^+] = K_1\frac{[acid]}{[salt]}$$

This is known as *Henderson's equation*, and it has great importance in physiology. It signifies that in a buffer system hydrogen ion concentration is dependent on the relative concentrations of the weak acid and its salt; or, conversely, that a change in the concentration of the acid or the salt modifies the hydrogen ion concentration.

Hasselbalch's equation expresses the same fact in terms of pH. Converting Henderson's equation into the reciprocal we have

$$\frac{1}{[H^+]} = \frac{1}{K_1} \times \frac{[salt]}{[acid]}$$

which can be expressed logarithmically as

$$\log\frac{1}{[H^+]} = \log\frac{1}{K_1} + \log\frac{[salt]}{[acid]}$$

The first term of this equation is the pH; $\log\frac{1}{K_1}$ can be expressed as pK_1, so we have

$$pH = pK_1 + \log\frac{[salt]}{[acid]}$$

This is Hasselbalch's equation; it has the same significance as Henderson's equation, from which it is obtained. Its importance will be seen when considering the acid-base equilibrium.

These systems are known as buffer systems because they modify the effects on the cH^+ of the addition of acid or base. For example, if 1 cc. 1 N HCl is added to 1 liter of water, a 0.001 N HCl solution is obtained. At this dilution the HCl is almost completely dissociated, so the cH^+ will be $0.001 = 10^{-3}$ and the pH = 3. If the same amount of HCl is added to a buffer system, *e.g.*, acetic acid–sodium acetate, the H^+ dissociated from the HCl are in the presence of an excess of $Acet^-$ dissociated from the sodium acetate, and a large number of nondissociated acetic acid molecules are formed. Only a few H^+ originated in the dissociation of acetic acid remain in solution, so there is little change in the real acidity of the solution.

There are many buffer systems in the organism contributing to the maintenance of a stable cH^+. The most important are the following (base, mainly Na and K, is expressed by the letter B):

$$H_2CO_3 : BHCO_3$$
$$BH_2PO_4 : B_2HPO_4$$
$$HHbO_2 : BHbO_2$$
$$HHb : BHb$$
Proteins also form a buffer system, since at the pH range of the organism they behave as weak acids:

H protein : B protein
When there are several buffer systems in a solution (as occurs in blood), changes in the concentration of one of the constituents of one system provoke changes in all the others, because of the shift in cH^+. Thus interdependent equilibriums between the different buffer systems are established.

CHAPTER 30

The Transportation of Carbon Dioxide by the Blood

ROLE OF THE BLOOD PLASMA

If a strong acid is added to "true" plasma (see Chap. 31) and then it is placed in a vacuum, from 50 to 70 cc. of CO_2 is obtained from each 100 cc. of plasma.

Approximately 5 per cent of the CO_2 is in solution in the form of carbonic acid (H_2CO_3); the rest forms an aqueous solution of bicarbonate. The former is known as free CO_2 and the latter as combined or fixed CO_2.

Applying Henderson's equation we have

$$[H^+] = K_1 \frac{[H_2CO_3]}{[BHCO_3]}$$

From this it can be seen that the cH^+ is dependent on the ratio of free CO_2 to combined CO_2, and conversely this ratio is dependent on the cH^+.

When arterial blood comes into contact with the tissues at the level of the capillaries, CO_2 enters the blood and the numerator in Henderson's equation tends to increase; therefore the cH^+, or real acidity of the blood, also tends to increase. Other buffer systems immediately come into action which check this tendency toward acidity, *e.g.*, the systems

$$\frac{BH_2PO_4}{B_2HPO_4} \quad \text{and} \quad \frac{\text{H protein}}{\text{B protein}}$$
The entrance of CO_2 and the shift toward acidity provoke the establishment of new equilibriums in these systems:

$$H_2CO_3 + HB_2PO_4 \rightleftarrows BHCO_3 + BH_2PO_4$$
$$H_2CO_3 + \text{B protein} \rightleftarrows BHCO_3 + \text{H protein}$$
An increase in CO_2 causes a shift toward the right in these reactions and therefore an increase in the bicarbonate of the plasma, which buffers the shift toward acidity in the acid-base equilibrium, *i.e.*, it controls the increase in cH^+. In the lung capillaries CO_2 passes from the blood to the alveolar air, and the changes in the plasma are opposite to those taking place in the tissue capillaries.

The buffer systems in the plasma are, however, of limited efficiency in the control of the acid-base equilibrium; whole blood is much more efficacious.

ROLE OF THE ERYTHROCYTES

Whole blood is collected and clotting prevented (*e.g.*, by adding sodium citrate); it is then brought to equilibrium with a gas mixture in which there is a high CO_2 tension. It is centrifuged under a layer of liquid paraffin to prevent gas exchanges at its surface. Plasma thus obtained has a high bicarbonate content. This fact was observed in 1867 by Zuntz. Under these conditions base has apparently passed from the cells to the plasma, but this is not so, because Hamburger has demonstrated that the erythrocyte membrane is not permeable to Na^+ and K^+. A rather complicated series of shifts take place, which is known as the Zuntz-Hamburger phenomenon.

The erythrocyte membrane is only slightly permeable to cations, such as Na^+, K^+, Ca^{++}, etc., but as Gürber showed in 1895, it is permeable to HCO_3^- and Cl^-. It is also permeable to H^+ and not permeable to hemoglobin.

The cells contain K^+ and hemoglobin, the latter being more acid when saturated with O_2

(HbO_2) than when in the reduced condition (Hb).[1] Therefore hemoglobin gives up cations (especially K^+) more readily than HbO_2.

Taking these facts into account a diagrammatic representation (Fig. 143) of what takes place can be made. This diagram only describes approximately the salient features and practical results of the changes in the different dynamic equilibriums. It is necessary to bear in mind that the liberation and fixation of ions are conditioned by interdependent equilibriums, which respond to the mass law.

As the blood passes through the tissue capillaries, its CO_2 concentration increases and HbO_2 diminishes, being converted into hemoglobin by loss of O_2. Hemoglobin is less acid and liberates K^+ more readily than HbO_2, fixing H^+ in its place. CO_2 entering the plasma combines with water and forms H_2CO_3, which dissociates (but not much) into HCO_3^- and H^+.[2] The H^+ enters the erythrocytes (and the cH^+ of the plasma diminishes) and is fixed by hemoglobin, taking the place of the K^+ set free. HCO_3^- also enters the red cells and combines with K^+, forming $KHCO_3$. In the plasma there is also dissociated NaCl, so Cl^- enters the red cells (Cl increases in the cells) and combines with K^+ into KCl; the Na^+ in plasma is balanced by the increase in HCO_3^-, and sodium bicarbonate increases. The increase in base observed in the plasma is therefore due not to a passage of base from the cells to the plasma, but to the passage of Cl^- from the plasma to the cells, which leaves an excess of cations in plasma. Therefore it would be more exact to say that there is a decrease in plasma anions (Cl^-) than that there is an increase in plasma cations (Na^+). Moreover, as CO_2 concentration increases in the blood, water passes from the plasma into the erythrocytes and the erythrocyte volume increases.

Changes in the opposite direction are observed in the lung capillaries. Oxygen enters the blood from the alveolar air and combines with hemoglobin, forming the more acid HbO_2, which sets free H^+; the H^+ diffuses out of the red cells into the plasma. Hemoglobin takes up K^+ from $KHCO_3$ and KCl. The anions of these salts, HCO_3^- and Cl^-, which had entered the cells as the blood changed from arterial to venous blood in its passage through the tissue capillaries, now return to the plasma. HCO_3^- is eliminated as CO_2 into the alveolar air, together with part of the CO_2 dissolved in the plasma. There is therefore an excess of Na^+, set free from the $NaHCO_3$; these Na^+ ions are balanced by the negative charges of the Cl^- ions diffusing out of the erythrocytes, which decrease in volume because water passes out of them into the plasma.

In tissues | In lung
FIG. 143. Gaseous and ionic equilibrium between the erythrocytes and blood plasma (the Zuntz-Hamburger phenomenon). Explanation in text.

Hemoglobin plays an important, although indirect, part in the carriage of CO_2; reduced hemoglobin, which is less acid than HbO_2, favors the fixation of CO_2; HbO_2 formed in the lung capillaries favors the liberation of CO_2. This can be expressed as follows:

$$KHbO_2 + H_2CO_3 \underset{\text{In the lungs}}{\overset{\text{In the tissues}}{\rightleftharpoons}} KHCO_3 + HHb + O_2$$
Reduction of HbO_2 to Hb *ipso facto* allows the blood to fix a larger amount of CO_2. The importance of this factor in the carriage of CO_2 by the blood is great, since it is responsible for 50 per cent of the CO_2 carried from the tissues to the lungs. It must be understood that this does not mean half the total CO_2 in blood, but half the CO_2 that is to be eliminated by the lungs, *i.e.*, half the difference between the arterial and venous CO_2.

CO_2 is formed in the tissues by the oxidation of C atoms in metabolites and is eliminated as gaseous CO_2 by the lungs. A small amount

[1] The isoelectric point of hemoglobin is at pH 6.78, and that of HbO_2 at pH 6.6.

[2] The process is in truth more complicated because H_2CO_3 is a pseudoelectrolyte and exists only as dissolved CO_2 or dissociated H_2CO_3. For the sake of simplicity the process is described as if carbonic acid were not a pseudoelectrolyte.

circulates in simple solution but the greater part is in the state of bicarbonate ion. The following reaction takes place in the tissues:

$$CO_2 + H_2O \rightarrow HCO_3^- + H^+$$
The reverse occurs in the lungs.

At the pH of the blood, the formation of CO_2 from H_2CO_3 and the shift in the opposite direction take place at a very slow rate. The passage through the lung capillaries takes only approximately 1 sec.; therefore if H_2CO_3 in blood were in the same conditions as in an aqueous solution of the same pH, less than 1 per cent of the CO_2 eliminated could be set free in that short time. In the lung capillaries CO_2 is set free very rapidly, almost "explosively." This is due to two causes: (*a*) the formation of carbamino compounds with hemoglobin; (*b*) the existence of an enzyme, carbonic anhydrase, in the erythrocytes, which catalyzes the reaction $CO_2 + H_2O \rightleftarrows H_2CO_3$ in both directions.

Carbamino compounds. CO_2 (but not H_2CO_3, HCO_3^-, or CO_3^{--}) combines with amines and forms carbamino compounds. The carbamino reaction can be expressed as follows:

$$CO_2 + RNH_2 \rightleftarrows RNH - COOH \rightleftarrows RNH - COO^- + H^+$$
The velocity of this reaction in different conditions (pH, temperature, etc.) has been determined for many simple amines. Carbamino compounds do not precipitate with calcium and barium salts, so they can be easily separated from solutions that also contain carbonates or CO_2.

The following facts are evidence that a carbamino reaction takes place in the blood:

1. At a physiologic pH, solutions of pure hemoglobin fix CO_2 proportionally to the hemoglobin concentration; oxygenation of hemoglobin diminishes the amount of CO_2 taken up.
2. The CO_2Hb compound is not precipitated by $BaCl_2$, therefore CO_2 is neither in solution nor as bicarbonate ion.
3. The dissociation curve of CO_2Hb in function of time is the same as that of carbamino compounds of simple amines.
4. Curves of absorption and liberation of CO_2 by blood in which carbonic anhydrase has been inhibited by HCN (see further on) are similar to the curves observed with solutions of simple amines.
5. After precipitation of CO_2 and bicarbonate by $BaCl_2$ there is still a residual fraction of CO_2 proportional to the hemoglobin content.

Liberation of CO_2 from the carbamino compound of hemoglobin takes place at a rapid rate and is favored by oxygenation of hemoglobin.

Carbonic anhydrase. According to the classical theory, CO_2 is carried in the blood as free (dissolved) CO_2 and as bicarbonate. CO_2 in simple solution diffuses rapidly and can also be rapidly set free in the short time the blood takes to pass through the lung capillaries. On the other hand this theory gives no satisfactory explanation of the "explosive" liberation of CO_2 from bicarbonate that takes place in the lung, because at the pH of the blood CO_2 is set free from aqueous solutions of bicarbonate at a very slow rate. Therefore it was necessary to postulate that (*a*) CO_2 is at least in part carried in some other combination, not bicarbonate; (*b*) a catalyzer accelerates the liberation of CO_2 from bicarbonate.

Both these mechanisms have been demonstrated. The first is the formation of carbamino compounds explained in the preceding paragraph. The second is carried out by an enzyme in the erythrocytes, carbonic anhydrase, which accelerates the reaction

$$H^+ + HCO_3^- \rightleftarrows CO_2 + H_2O$$
A buffer system that contains H_2CO_3, at the pH of the blood, rapidly sets free CO_2 on addition of hemolyzed erythrocytes. The active fraction separated from the red cells has no hemoglobin, or hematin, and its activity is not due to catalase, peroxidase, or oxidase. The purified enzyme accelerates the liberation of CO_2 even when diluted 1 in 10,000,000. Carbonic anhydrase is inhibited by HCN, H_2S, CO, and several metal ions (Cu, Ag, Au, Zn, Hg).

The importance of the erythrocytes in the carriage of CO_2 is thus further enhanced, and the explanation of the Zuntz-Hamburger phenomenon must be completed as is illustrated in Fig. 144.

The total amount of CO_2 set free from the blood as it passes through the lungs[1] of a subject at rest can be divided approximately into the following fractions:

[1] Not the total amount of CO_2 in the blood; this has another significance, which will be considered in the next chapter when dealing with the alkali reserve.

Dissolved CO_2 . . . . 10 per cent
Carbamino compounds of hemoglobin . . . . 20 per cent
Bicarbonate CO_2, set free by the action of carbonic anhydrase . . . . 70 per cent

CO_2 dissociation curves. A solution that contains CO_2, dissolved or combined (carbonates and bicarbonates), sets free CO_2 when a strong acid is added and it is then placed in a vacuum. The method most commonly used to determine the CO_2 content of organic fluids is that of van Slyke *et al.*, in which a measured volume of fluid is submitted to the effects of an acid and vacuum. The volume of all the gases set free is measured at atmospheric pressure;[1] a solution of NaOH is added to absorb the CO_2 and the gases are again measured. The difference between the two measurements gives the CO_2 content. The measurements should be corrected for NTP (*i.e.*, 0°C. and 760 mm. pressure).

CO_2 content can be expressed in several ways (*e.g.*, moles per liter), but in biology and medicine it is usual to give it in volumes of CO_2 per cent; *e.g.*, a blood CO_2 content of 55 volumes per cent means that 100 cc. of blood sets free 55 cc. CO_2 (at NTP) when submitted to the action of an acid and a vacuum.

[1] Van Slyke's manometric method is based on a different principle (see technical manuals).

CO_2 can be obtained from a solution by simple evacuation without adding acid, but in this case the carbonates dissolved do not set free CO_2. A solution of sodium bicarbonate sets free half its CO_2:

$$2NaHCO_3 \rightleftarrows CO_2 + H_2O + Na_2CO_3$$
This is a reversible reaction; therefore a solution of sodium carbonate in an atmosphere of CO_2 fixes this gas with the formation of $NaHCO_3$.
FIG. 144. Interchange of gases and ions between the erythrocytes, blood plasma, and alveolar air. Explanation in text. (*After Roughton.*)

Blood and other organic fluids in contact with gaseous mixtures of different CO_2 content take up or set free CO_2, according to the partial pressure of CO_2, until an equilibrium is established. For this reason the CO_2 content of blood has no precise significance if the CO_2 tension with which it is in equilibrium is not known.

A sample of blood (kept fluid by an anticoagulant) is divided into several fractions, each of which is brought to equilibrium with a gaseous mixture at different CO_2 partial pressures; then the CO_2 content of the blood of each fraction is determined. The results plotted on an *x-y* graph give the CO_2 dissociation curve. Examples of these curves are given in Fig. 145. The lower curve was obtained with blood brought into equilibrium with air of different CO_2 tensions; the upper curve with the same blood brought into equilibrium with mixtures of CO_2 and H_2. Hemoglobin in the blood corresponding to the lower curve was almost com-

pletely oxygenated (HbO_2), while in the blood of the upper curve it was almost completely reduced (Hb).

Several facts can be deduced from the examination of these curves. At the same CO_2 tension, blood with reduced hemoglobin (Hb)
FIG. 145. CO_2 absorption curves of blood at different CO_2 partial pressures. The higher of the two curves corresponds to blood with reduced hemoglobin, and the lower to blood with oxygenated hemoglobin. The straight line at the bottom corresponds to CO_2 in solution.

fixes more CO_2 than blood with oxygenated hemoglobin (HbO_2). This is due to the lower acidity of hemoglobin, which permits it to fix a larger amount of H^+ and set free more K^+, and to the greater ease with which it enters into carbamino reactions.

Blood placed in a vacuum, or brought into equilibrium with a gas mixture without CO_2 (CO_2 partial pressure = 0), sets free all its CO_2, but plasma separated from the red cells does not. Therefore in whole blood—more precisely, in the erythrocytes—there must be a weak acid that can take care of the excess cations remaining after the elimination of CO_2 from bicarbonate. This weak acid that replaces HCO_3^- is hemoglobin.

Separated plasma also has several systems that can hold part of the excess Na^+, such as phosphate, proteinate, etc.; *e.g.*,

$$NaH_2PO_4 + NaHCO_3 \rightarrow Na_2HPO_4 + CO_2 + H_2O$$
These systems, however, are not sufficient to permit the liberation of all the CO_2.

The part of the CO_2 dissociation curve that is of greatest interest is that corresponding to the CO_2 tensions found in arterial and venous blood. As an example, let us take normal human blood with a CO_2 content of 52 volumes per cent in arterial and 57 volumes per cent in venous blood, and with 40 and 48 mm. Hg partial pressure respectively, and then examine Fig. 146, which is the section of Fig. 145 corresponding to the "physiologic" range of CO_2 tension.

The "arterial point" *A* on the lower curve corresponding to oxygenated blood lies at 40 mm. Hg CO_2 tension and 52 per cent CO_2 content. As blood passes through the capillaries, HbO_2 is reduced and CO_2 enters from the tissues, so that a "venous point" *V*, corresponding to 48 mm. Hg CO_2 tension and 57 per cent CO_2 content, is reached. On passing through the tissue capillaries, the blood has taken up 5 volumes per cent CO_2. If only the partial pressure of CO_2 varied, other circumstances remaining unaltered, the partial pressure would have had to rise to 52 mm. Hg (*B* on the lower curve) to obtain the increase of 5 volumes per cent in the CO_2 content. If this had taken place, dissolved CO_2 would have increased, and according to Henderson's equation, the cH^+ would
FIG. 146. Normal range of the curve in Fig. 145. Description in text.

have also risen. Partial reduction of hemoglobin causes the venous point to be at a lower CO_2 tension, therefore hemoglobin plays a part in maintaining the constancy of the acid-base equilibrium in the blood, damping the oscillations in pH.
FIG. 147. Henderson's nomogram of human blood. Eight interdependent variables are represented in order from left to right: 1, ratio of plasma volume to total volume; 2, ratio of cell Cl to plasma Cl; 3, total CO_2 in volumes per cent; 4, CO_2 pressure in mm. Hg; 5, pH of plasma; 6, pH of erythrocytes; 7, O_2 pressure in mm. Hg; 8, HbO_2 expressed as volumes of O_2 per cent. (*Henderson, L. J., "Blood," Yale University Press, New Haven, 1928.*)

INTERDEPENDENT EQUILIBRIUMS. HENDERSON'S NOMOGRAMS

The student can now understand how changes in one component of the blood cause changes in many closely interdependent equilibriums. L. J. Henderson has made a particular study of these equilibriums. He considers that between both phases of the blood (plasma and cells) there are eight components, four of which can be distributed in varying proportions between both phases (water, carbonic acid, chloride, and oxygen); two are found only in plasma (plasma proteins and plasma base); and two are found only in the cells (hemoglobin and cell base).

Two of these components, oxygen and carbonic

acid, are independent variables; changes in the other components are subject to variations in these two. Changes in the eight components cause changes in other variables such as pH (dependent on the variables free CO_2 and combined CO_2), the Donnan equilibrium, the red cell volume, etc.

Henderson has determined experimentally the interdependence of these variables and expressed their relationship mathematically. Nomograms (Greek, *νομος*, law, and *γράμμα*, written) can be constructed so that the different variables are represented in a system of coordinates (D'Ocagne's nomograms) and their relationship rapidly understood. The number of variables in some of Henderson's nomograms is 18; in the one reproduced in Fig. 147, eight interdependent variables are represented.

THE ROLE OF CO_2 IN THE BODY

CO_2 is the end product of carbon metabolism in the animal organism, and it is eliminated as a waste product. Nevertheless some remains so as to maintain a certain level of CO_2 concentration in the fluids and tissues, which is of great physiologic importance. CO_2 combined with Na in $NaHCO_3$ forms the alkali reserve; furthermore a certain amount of free CO_2 is necessary for an adequate cH^+. Therefore excessive elimination of CO_2 may cause severe disturbance, *e.g.*, alkalosis (see "The Alkali Reserve," Chap. 31, and Chap. 32, Regulation of Respiration.)

CO_2 also plays an important part in organic synthesis. In plants it is the only source of C. The activity of chlorophyll and energy obtained from sunlight are the means used by plants to reduce CO_2 and thus have C for the synthesis of the organic compounds that make up the plant (cellulose, starch, proteins, oils, alkaloids, etc.).

Using a radioactive carbon isotope (C^{11}) to label CO_2, it has been possible to demonstrate that CO_2 gives up C in the synthesis of many compounds by bacteria or animal tissues, *e.g.*, methanol; urea; propanol; formic, acetic, pyruvic, lactic, propionic, oxalacetic, succinic, fumaric, malic, butyric, α-ketoglutaric, oxalsuccinic, and citric acids; and glycogen (Wood). In rats injected with sodium bicarbonate prepared with C^{11}, 13 per cent of the carbon in liver glycogen was found to be C^{11}.

CHAPTER 31

The Acid-Base Equilibrium of the Organism

THE ALKALI RESERVE

In an aqueous solution of electrolytes the total positive charges are equal to the total negative charges; in other words, the total concentration of positive equivalents is equal to the total concentration of negative equivalents. Thus the electric neutrality of the solution is maintained. For example, in a NaCl solution, for each Na^+ there is one Cl^-; in a $CaCl_2$ solution, for each Ca^{++} there are two Cl^-. One equivalent is equal to one mole for monovalent ions; but for polyvalent ions one equivalent is equal to one mole divided by the number of valences. Thus one mole of Ca^{++} weighs 40 gm., and one equivalent of Ca^{++} weighs $40/2 = 20$. Therefore 20 gm. Ca^{++} is the equivalent of 35.5 gm. Cl^-, *i.e.*, in a solution containing these amounts of Ca and Cl there is the same number of positive charges (Ca^{++}) as of negative charges (Cl^-).

Electric neutrality, or electric equilibrium, is also maintained in complex solutions of electrolytes, such as blood plasma. The part taken by each of the ions is established by determining their concentration by chemical analysis, and their equivalents (usually milliequivalents when working with blood plasma) are obtained by applying the following formula:

$$\text{mEq. per liter} = \frac{\text{Mg. per liter} \times \text{valence}}{\text{Molecular weight}}$$

The concentration of the principal ions in plasma is given in Table 27 (Fig. 148). In this table and figure it can be seen that the negative charges are carried by strong acids (HCl, H_2SO_4) and by weak acids (H_2CO_3, acid phosphate and proteinates). The former, because of their strength, cannot be displaced from their base by acids formed in the course of the normal or abnormal metabolism of the body; the latter, on the other hand, can be displaced. For example, during strenuous muscular exercise the concentration of lactic acid in the blood increases considerably; this acid takes Na from $NaHCO_3$, and thus sets free H_2CO_3, which is eliminated as CO_2 by the lungs. There is, therefore, an alkali reserve in the blood that can neutralize the acid valences formed in the body. This alkali reserve is made up by the base of weak acid salts. The most important of these acids is carbonic acid, owing to the ease with which it is eliminated as CO_2 by the lungs. The alkali reserve of the blood is usually measured by determining the bicarbonate content of the plasma.

Table 27. Normal Content of Positive (Base) and Negative (Acid) Ions in Human Plasma

Base ions	*Content, mEq. per liter*		Acid ions	*Content, mEq. per liter*	
	Range	*Average*		*Range*	*Average*
Na^+	136.0–144.0	142	HCO_3^-	25.0–27.0	27
K^+	4.0–5.0	5	Cl^-	98.0–106.0	103
Ca^{++}	4.8–5.2	5	HPO_4^{--}	1.8–2.5	2
Mg^{++}	2.5–3.5	3	SO_4^{--}	0.8–1.2	1
			Organic	4.0–8.0	6
			Proteins	14.0–18.0	16
Total		155	Total		155

The bicarbonate content of plasma can be expressed in several ways, *e.g.*, in milligrams per cent or in millimoles per liter, but it is customary

to express it in centimeters (or volumes) of CO_2 per cent, because it is determined by the volume of CO_2 set free from the plasma by a strong acid *in vacuo*. The normal value lies between 50 and 70 volumes CO_2 per cent.
Fig. 148. Diagram of average content of anions and cations in human blood expressed in milliequivalents per liter.

Determination of the alkali reserve. The ease with which CO_2 diffuses out of the plasma into the air should be kept in mind when measuring the alkali reserve, because if adequate precautions are not taken the balance between the CO_2 in the plasma and that in the cells is disturbed, and errors are thus committed. The significance of certain terms in common use should be clearly understood.

True plasma is obtained from blood under conditions in which no changes in its gaseous content can occur. The blood must be centrifuged under a layer of paraffin oil so that gas cannot escape from the surface into the air, thus causing an interchange of ions between erythrocytes and plasma. After centrifuging, the plasma is pipeted off and placed in a saturating vessel. This true plasma, obtained from venous or arterial blood, can be equilibrated with the subject's own alveolar air; it is then called "regularized plasma." If it is equilibrated with a gaseous mixture containing 5.5 per cent CO_2, corresponding to a CO_2 tension of 40 mm. Hg, which is the average CO_2 tension in alveolar air of man, it is called "reduced plasma."

The following procedure is most commonly used: About 12 cc. of blood is drawn from a vein in the arm, taking care to avoid stasis and the accumulation of CO_2 in the blood, as this would cause an increase in plasma bicarbonate due to the chloride shift between the red cells and plasma, as explained in Chap. 30. The blood is collected in a syringe containing a small number of sodium oxalate or citrate crystals to prevent clotting, and is passed into a centrifuge tube under a layer of liquid paraffin. After centrifuging, 4 or 5 cc. is pipeted off, placed in a saturation flask (Fig. 149), and equilibrated with CO_2 at the same tension as in arterial blood by filling the flask with the subject's own alveolar air or a gas mixture with 5.5 per cent CO_2. In the first case the subject makes a forced expiration (after a normal inspiration) into the saturation flask through another flask containing glass beads to retain the moisture in the expired air. The saturation flask is then closed at both ends. If 5.5 per cent CO_2 is used, about 1 liter of the gas mixture is passed through the flask. The flask is gently
Fig. 149. Saturation flask. A few cubic centimeters of blood is placed in the flask and this is then filled with a gas mixture of known composition with which the blood is to be brought into gaseous equilibrium. The flask is closed at both ends and is gently rotated so as to distribute the blood along its walls, thus increasing the surface of contact between gas and blood. The bottle with glass beads is used to retain water vapor when the flask is filled with expired air; the bottle is disconnected after closing the flask by turning the stopcock.

rotated during 2 min. so that there is a large surface of contact between the air and plasma. Afterward 3 cc. of plasma is placed in a van Slyke gas apparatus, where CO_2 and other gases are set free from the plasma by adding a strong acid and producing a vacuum. The gas is brought to atmospheric pressure and measured, making the corrections for NTP. Not only CO_2 but also N_2 and O_2 are thus liberated, but the two latter are fairly constant, so the part corresponding to CO_2 can be read off in especially constructed tables. Technical manuals should be consulted for further details and for van Slyke and Neill's manometric method.

The CO_2 volume thus measured corresponds to the bicarbonate in plasma and is also called the carbon dioxide "combining power," or "capacity," of the plasma. This volume calculated for 100 cc. of plasma is the usual way of expressing the alkali reserve of the plasma. The normal figure is 50 to 70 volumes per cent. Unless special mention is made of the use of whole blood, lymph, pleural effusion, etc., it is understood that this figure corresponds to a determination made on venous blood plasma.

The alkali reserve is one of the constant properties of the organism, in the same way as the body temperature, blood-sugar level, etc. In normal conditions it does not vary to any considerable extent.

THE ACID-BASE EQUILIBRIUM

Two constants have importance in the study of the acid-base equilibrium, the hydrogen ion concentration, expressed by the pH, and the alkali reserve. These can vary independently of each other, since the pH is not dependent on the bicarbonate content but on the ratio of bicarbonate to carbonic acid.

In a buffer system consisting of bicarbonate and carbonic acid, the pH is conditioned as follows according to Hasselbalch's equation:

$$\mathrm{pH} = pK_1 + \log \frac{[\text{Bicarbonate}]}{[\text{Carbonic acid}]}$$

As bicarbonate is measured by the CO_2 set free, the last part of the second member of the equation can be replaced by the logarithm of

$$\frac{[\text{Combined } CO_2]}{[CO_2 \text{ in solution}]}$$

Since $pK_1 = 6.10$, if two of the remaining variables are known the third can be calculated.

The amount of CO_2 in solution is dependent on its partial pressure, which can be measured in the alveolar air. The absorption coefficient of CO_2 in plasma at 38°C. is 0.51. If the CO_2 partial pressure is 40 mm. Hg, the volume of CO_2 dissolved in 100 cc. at a barometric pressure of 760 mm. will be

$$40/760 \times 100 \times 0.51 = 2.68 \text{ volumes per cent}$$

If the total CO_2 in plasma amounts to 63 volumes per cent, and the CO_2 in solution is 3 volumes per cent, there will be 60 volumes per cent combined CO_2; the ratio in Hasselbalch's equation will be $60/3 = 20$. But $\log 20 = 1.30$; therefore $\mathrm{pH} = 6.1 + 1.30 = 7.4$. In normal conditions for each volume of CO_2 in solution there are approximately 20 volumes of combined CO_2, *i.e.*, 5 volumes of free CO_2 for every 100 volumes of combined CO_2. The volumes of CO_2 in solution per 100 volumes of combined CO_2 at different pH levels are given in Table 28.

Table 28. Free CO_2 for Each 100 Volumes of Combined CO_2 at Different pH

pH	*Free CO_2, Volumes*
7.0	12.5
7.3	6.3
7.4	5
7.5	4
7.8	2

The pH of the blood can therefore be determined by this indirect method, but it is not usually adopted because it is more complicated than the potentiometric and indicator methods.

A decrease in plasma bicarbonate is not accompanied by a change in pH if enough CO_2 is eliminated by the lungs to maintain the ratio of 1:20 between free and combined CO_2. This condition is known as compensated acidosis (see page 285). In a similar way ingestion of bicarbonate in sufficient quantities to increase its concentration in the blood does not modify the pH if at the same time enough CO_2 is retained to maintain a 1:20 ratio between free and combined CO_2. In this case there is compensated alkalosis.

These facts show the importance of pulmonary ventilation and the excitability of the respiratory center in the maintenance of a normal acid-base equilibrium and in some conditions in which it is disturbed.

The acid that is formed in greatest amounts in the body as a result of metabolic activity is

carbonic acid; from 400 to 460 liters, or 800 to 900 gm. of CO_2, is produced daily. These large amounts, however, do not disturb the normal acid-base balance because of the ease with which the lungs eliminate CO_2 as it is formed.

librium. The alkali reserve and the pH can be normal, or high, or low, and by the combination of these conditions of each of two factors, nine different cases are possible. They will be discussed in the following pages. The existence of
FIG. 150. Normal and pathologic variations in $BHCO_3$, H_2CO_3, CO_2 pressure, and pH in total human blood obtained from a resting subject at sea level. The curves represent CO_2 dissociation; the upper curve corresponds to reduced blood and the lower one to oxygenated blood. The straight line in the lower part of the diagram represents the CO_2 in solution, which is directly proportional to the partial pressure of CO_2. The other straight lines represent the pH calculated from the ratio of $BHCO_3$ to H_2CO_3 (combined CO_2 to free CO_2) of Hasselbalch's equation. The total combined CO_2 corresponding to any point on the pH lines is obtained by subtracting CO_2 in solution from total CO_2. For example, on the line corresponding to pH 7.0 at 107 mm. Hg CO_2 partial pressure, the total combined CO_2 is $60 - 6.7 = 53.3$. The ratio of dissolved CO_2 to combined CO_2 is 12.5 per cent. This ratio corresponds to pH 7.0 according to Hasselbalch's equation. This ratio is constant for all the points on the line; therefore the pH lines are straight ones. The nine areas separated by the different lines and curves are described in the text. (*Van Slyke, D. D., J. Biol. Chem., vol. 48, p. 157, 1921.*)

Venous blood is slightly more acid than arterial blood; there is a difference in pH of 0.02 between the two. This slight difference would be much larger if it were not for the mechanism described as the Zuntz-Hamburger phenomenon (Chap. 30).

The normal range of pH is from 7.3 to 7.5; extreme variations compatible with life are 7.0 and 7.8.

Disturbances in the acid-base equilibrium. Acidosis and alkalosis. The alkali reserve and the pH—two factors that vary independently of each other—should be determined when considering disturbances in the acid-base equilibrium. The alkali reserve and the pH can be normal, or high, or low, and by the combination of these conditions of each of two factors, nine different cases are possible. They will be discussed in the following pages. The existence of these two variables has caused some confusion as to the exact significance of "acidosis" and "alkalosis." The term "acidosis" does not mean that the blood is acid, since a pH below 7 is incompatible with life. Used in a less precise way, it signifies a decrease in pH or the alkali reserve, and "alkalosis" signifies the opposite conditions. This ambiguous use of the word "acidosis" occurs in van Slyke's definition; he considers that acidosis is due to the formation or absorption of acids at a rate that exceeds their rate of elimination, so that either the hydrogen ion concentration in the blood increases, or the alkali reserve decreases below the normal range.

To avoid confusion some authors do not employ the terms "acidosis" and "alkalosis," but as they are in common use, it is necessary to give them a definite meaning. They may therefore be defined as variations of the alkali reserve outside the normal range. If in acidosis, thus defined, the pH is normal (owing to an adequate decrease in free CO_2) the condition is one of compensated acidosis; if the pH falls below 7.3, there is uncompensated acidosis. The corresponding opposite states are known as compensated and uncompensated alkalosis.

The nine possible states produced by the three variants in the two factors have been described by van Slyke, who calls them "alkali or CO_2 excess, compensated or uncompensated, with high or low pH" (Figs. 150 and 151).

Possible variations in acid-base equilibrium (according to van Slyke).[1] *Area* 1. *Uncompensated alkali excess.* In this condition, bicarbonate ($NaHCO_3$) is increased without a corresponding increase in H_2CO_3, so the pH rises above the normal. This condition can be produced by excessive ingestion of sodium bicarbonate, or by the loss of HCl as a result of repeated vomiting or stomach washing. If the pH rises sufficiently, tetany may appear. Compensation is brought about by a decrease in active pulmonary ventilation, which causes retention of CO_2, and an increase in the renal excretion of bicarbonate and alkaline phosphate.

Areas 2 *and* 3. *Uncompensated CO_2 deficit.* Free $CO_2(H_2CO_3)$ is decreased without a proportionate decrease in combined $CO_2(NaHCO_3)$, so the pH increases. This disturbance is provoked by hyperpnea, such as is caused by lack of oxygen at high altitudes, or by hot baths, or by fever. If the pH rises sufficiently, tetany appears. Compensation takes place by the accumulation of acid metabolites, and by a decrease in the acidity or the alkalinization of the urine. Sometimes this condition is called "respiratory alkalosis" because it is due primarily to loss of free CO_2, which is eliminated by the lungs as a gas.

Area 4. *Compensated CO_2 or alkali excess.* In this condition there is a parallel rise in free carbon dioxide (H_2CO_3) and combined carbon dioxide ($NaHCO_3$); there is a high alkali reserve and the pH is within the normal range (*i.e.*, the disturbance is compensated). It is produced by the same causes that provoke the disturbance in area 1, but in a lesser degree, *i.e.*, ingestion of sodium bicarbonate with subsequent CO_2 retention, or primary retention of CO_2 as occurs in certain chronic diseases of the lung that hinder the gaseous exchange (emphysema) with secondary retention of $NaHCO_3$. If the disturbance is due to pulmonary disease, there is cyanosis due to insufficient oxygen absorption.
FIG. 151. Normal and pathologic variations in bicarbonate and pH of serum or oxalated plasma. This figure has the same significance as Fig. 150, but the pH is represented so as to facilitate distinction of the nine areas described in the text. Solid lines correspond to arterial blood and broken lines to venous blood. CO_2 is expressed not in volumes per cent but in millimolar concentration. As 1 mole of any gas has a volume of 22.4 liters (NTP), 1 millimole has a volume of 22.4 cc.; therefore a millimolar concentration of 1 corresponds to 22.4 cc. per liter, or 2.24 cc. per cent. (*Van Slyke, D. D., J. Biol. Chem., vol. 48, p. 157, 1921.*)

Area 5. *Normal acid-base equilibrium.* Combined (alkali reserve) and free CO_2 and the pH are normal at sea levels; at high altitudes the conditions vary (Chap. 33).

Area 6. *Compensated alkali or CO_2 deficit.* There is a proportionate decrease in combined and free CO_2; therefore the pH is normal. This condition can be initiated either by a deficiency of alkali or by a deficiency of CO_2. Alkali deficit can be due to excessive production of fixed acid metabolites (*e.g.*, ketone bodies), to retarded elimination of fixed acids (nephritis), to intoxication by acids that are not metabolized (HCl, H_2SO_4), to acidogenous salts,[1] or to excessive excretion of base, such as

[1] VAN SLYKE, D. D., Studies of Acidosis. The Normal and Abnormal Variations in the Acid-base Balance of the Blood, *J. Biol. Chem.*, **48,** 153, 1921.

[1] The more commonly used acidogenous salts are NH_4Cl and $CaCl_2$. The NH_4 is converted into urea, which is eliminated; thus acid Cl^- is released. In the

occurs in certain infantile diarrheas and in biliary and pancreatic fistulas.

An initial CO_2 deficit can be observed at high altitudes. It is due to hyperpnea (the typical sign of this condition) caused by the decrease in oxygen partial pressure.

When the initial cause is alkali deficit, it is compensated by an increase in the elimination of acids and ammonia in the urine (unless renal iniury prevents this) and a decrease in CO_2 partial pressure in alveolar air. When the initial cause is CO_2 deficit, there is an excess elimination of base through the kidneys until the free and combined CO_2 are in normal proportions. In high altitudes this is the compensatory reaction, and persons acclimatized to high altitudes have an alkali reserve below the normal one for sea level.

Areas 7 *and* 8. *Uncompensated CO_2 excess.* There is an increase in free CO_2 without a corresponding increase in base; therefore the pH is low. This condition is also known as "respiratory acidosis," because the initial disturbance is retention of free CO_2. It can be observed in pneumonia (a disease in which the respiratory surface of the lung is considerably diminished) in cases of intoxication by depressants of the respiratory center (*e.g.*, morphine), and in uncompensated cardiac insufficiency. Dyspnea is a prominent symptom of this state. Compensatory mechanisms are increased respiratory rate, renal excretion of acid metabolites with increased formation of ammonia, and perhaps diffusion of acids from the blood into the tissues.

Area 9. *Uncompensated alkali deficit.* There is a considerable decrease in blood bicarbonate, without a proportionate decrease in free CO_2; therefore the pH is low. This condition is observed in advanced diabetic coma, in the final stages of renal acidosis, in very deep anesthesia, and in certain forms of cardiac insufficiency. There is dyspnea, and compensatory reactions are the same as in uncompensated CO_2 excess, unless the condition is of renal origin, in which case the kidney does not take part in compensation.

Respiratory alkalosis and acidosis. Disturbances in pH due to variations in free CO_2 can cause acidosis (retention of CO_2) or alkalosis (excess elimination of CO_2). In the first case the condition corresponds to areas 7 and 8 of van Slyke's diagram, and in the second to areas 2 and 3. In these states the deficit or excess is due primarily to variations in free (gaseous) CO_2, represented in Hasselbalch's equation. For this reason these types of disturbance are known as respiratory acidosis or alkalosis. If acidosis is due initially to uncompensated loss of alkali (*i.e.*, a decrease in fixed CO_2), as in conditions corresponding to area 9, it is sometimes known as "metabolic acidosis."

case of $CaCl_2$ the cation is eliminated in large part as $CaCO_3$ through the intestine, and Cl^- is set free.

Changes in acid-base equilibrium are the results, or signs, of more or less serious conditions; they are not always a fundamental cause of the seriousness of the patient's condition. Two examples will make this clear. In diabetic coma there may be a considerable decrease in the alkali reserve; this can be increased by ingestion of sodium bicarbonate, thus reestablishing a normal acid-base equilibrium, but the seriousness of the patient's general condition remains unchanged. In deep asphyxia, in spite of the "acidosis" due to CO_2 retention, the appropriate treatment is to make the patient breathe a mixture of O_2 and CO_2 with the object of stimulating the respiratory center, thus alleviating the general condition.

MECHANISMS FOR THE REGULATION OF THE ACID-BASE EQUILIBRIUM

The normal range of blood pH is 7.3 to 7.45, and that of the alkali reserve is 50 to 70 volumes CO_2 per cent. Within these normal limits there are daily variations, the most important of which are due to muscular exercise (increased production of CO_2 and lactic acid) and to digestive processes (increase of the alkali reserve due to the secretion of HCl into the gastric juice). Besides these changes, the body is continuously producing acid or alkaline substances in the course of, and as a result of, the metabolism of foodstuffs.

Acid substances are produced in the following ways:

1. The oxidation of carbon gives rise to CO_2.
2. Proteins break down to amino acids, which are either resynthesized into protein or oxidized. Amino acids with sulfur in their molecule give sulfuric acid as a final product of disintegration.
3. Phospholipids and nucleoproteins give phosphoric acid; nucleoproteins also give rise to uric acid.
4. The disintegration of fats sets free fatty acids. These are normally burned down to CO_2 and water, but if complete combustion does not occur, ketone bodies are accumulated. Thus

with certain unbalanced diets and in some pathologic conditions, acetylacetic and β-hydroxybutyric acid are accumulated.

5. Lactic acid is formed in the course of glycogen metabolism, but it is resynthesized into glycogen.
6. Oxalic acid is a product of the metabolism of some foods such as cocoa and spinach.

The formation of acids is a necessary step in some metabolic processes; therefore some acids should not be considered as waste products.

Base set free in the organism is derived mainly from vegetable foodstuffs which contain salts of organic acids. For example, in the metabolism of sodium citrate the citrate is oxidized and Na is left over, which with CO_2 and H_2O forms sodium bicarbonate. The urine of herbivorous animals is alkaline, because there is an excess of base (K, Na, Ca, and Mg) in the final products of the metabolism of vegetable foodstuffs. When these animals are kept fasting, as in Claude Bernard's famous experiment, the urine becomes acid.

The two factors of acid-base equilibrium—pH and alkali reserve—are kept within the normal limits by the excretion of the excess acid or base. There are several mechanisms for this, but undoubtedly the body is better equipped for the neutralization and elimination of acid than for that of base.

Secretions must be divided into two groups: (*a*) those in which the product of secretion is normally reabsorbed (saliva, gastric juice, bile, pancreatic juice, etc.); (*b*) those in which the product of secretion is eliminated from the organism, as in the case of sweat. In normal conditions the acid-base balance is not finally dependent on secretions of the first group, but in pathologic conditions they may be the cause of serious disturbance; *e.g.*, repeated vomiting leads to loss of Cl^-, and the relative increase in Na^+ leads to alkalosis. A permanent biliary or pancreatic fistula results in loss of base, and if adequate precautions are not taken acidosis results.

There are five mechanisms that take part in the regulation of the acid-base equilibrium: the blood, the respiratory, renal, and intestinal mechanisms, and finally the tissues.

Mechanisms in the blood. These mechanisms have already been discussed. They consist of (*a*) buffer systems in the plasma; (*b*) hemoglobin; (*c*) the selective permeability of the red cell membrane (see Chap. 30).

Respiratory mechanism. The excitability of the respiratory center plays an important part in the regulation of the acid-base equilibrium, because an increase in pulmonary ventilation increases the elimination of CO_2, and a decrease has the opposite effect, thus maintaining constant within the normal limits the ratio of free CO_2 to combined CO_2, as expressed in Henderson's equation. The respiratory center is so sensitive that a rise of 1 mm. in CO_2 partial pressure causes a 60 per cent increase in pulmonary ventilation. Drugs that depress the respiratory center (*e.g.*, morphine) cause CO_2 retention. The respiratory regulation of the acid-base balance is closely related to the regulation of respiratory movements, which will be fully discussed in Chaps. 32 and 33, particularly under "Anoxia."

Renal mechanism. The lung is the principal route for the elimination of CO_2, and the kidneys for the elimination of fixed acid and base. Urine secreted by the kidney can vary considerably in pH; according to the physiologic circumstances the pH varies between 7.4 and 4.8. The kidney regulates the elimination of acids by the selective excretion of acids and by the formation of ammonia (see page 741).

Selective elimination of acids, with the formation of acid urine, occurs when acid waste products are formed in the course of normal or abnormal (ketone bodies) metabolism, and when fixed acids (sulfuric, chlorhydric, phosphoric) or acidogenous salts (ammonium chloride, $CaCl_2$) are ingested. The kidney has a limited capacity for concentrating acids (the urinary pH cannot be lower than 4.8). If larger amounts of fixed acids must be eliminated they must be accompanied by a proportionate quantity of base taken from the alkali reserve, which is thus depleted.

For example, if a subject drinks a certain quantity of a dilute solution of HCl (concentrated solutions are caustic) the acid is eliminated through the kidney, not simply as HCl, but neutralized; otherwise the urinary pH would fall below the maximum limit of 4.8. If the base used for this purpose is Na taken from plasma bicarbonate, the alkali reserve is diminished, but the kidney can form ammonia, which is used instead of fixed base; thus the alkali reserve is spared.

Buffer systems in urine. Any solution containing a weak acid and its salt is a buffer system. The urine contains several of these systems, of which the best known is the acid phosphate–basic phosphate system. Henderson's equation for this system is the following:

$$cH^+ = K_1 \frac{BH_2PO_4}{B_2HPO_4}$$

This system is also found in the blood, and if the urine is acid, as it usually is in man, the numerator increases and the denominator decreases. Acid phosphate is formed by the following process:

$$B_2HPO_4 + H_2CO_3 \rightarrow BH_2PO_4 + BHCO_3$$
The bicarbonate thus formed is retained in the organism and goes into the alkali reserve.

If this were the only renal mechanism for controlling the acid-base balance, at least part of the fixed base would be lost; especially Na and K would be excreted as acid phosphates. Another mechanism for sparing base is the formation of ammonia, which takes the place of Na and K in the neutralization of acid ions eliminated in the urine (see pages 742–743).

Usually, in man, urinary ammonia accounts for approximately 4 per cent of the total urinary N, but when more acid is formed or ingested, the urine not only becomes more acid, but ammonia content also rises and can account for as much as 20 per cent of total urinary N.

To assess the part played by the kidney in the elimination of acids, total urinary acidity (determined by titration and expressed in cubic centimeters of 0.1 *N* acid solution) and urinary ammonia (expressed as cubic centimeters of 0.1 *N* ammonia) should also be estimated. The sum of these factors gives the urinary acid excretion index, which is an indirect way of determining the degree of acidity of the organism. Of course, if there are infectious processes in the bladder caused by microorganisms capable of fermenting the urine and producing NH_3 at the expense of urea, this index loses significance.

Origin of urinary ammonia. Ammonia excreted in response to an excess formation of acid is formed in the kidney. The following facts are evidence of this: (*a*) the amount of NH_3 in blood (0.46 mg. per liter) is not sufficient to account for the large quantities of NH_3 secreted in the urine in acidosis; (*b*) experimental total nephrectomy does not cause an increase of blood NH_3; (*c*) venous blood leaving the kidney has a higher NH_3 concentration than arterial blood entering the kidney.

At one time it was thought that ammonia was formed in the kidney from urea in the blood. Van Slyke and his associates[1] have shown that in the dog the greater part is formed from glutamine. Acidosis was provoked by the ingestion of HCl, and a difference in the glutamine in renal arterial and venous blood was found, which could not be accounted for by excretion of glutamine, but which corresponded to the increase in urinary ammonia. Alkalosis provoked by the ingestion of sodium bicarbonate, on the contrary, caused a decrease in the glutamine removed by the kidney from the blood. A glutaminase which catalyzes the formation of NH_3 from glutamine has been found in renal tissue. Van Slyke suggests that, beside this main source of ammonia, amino acids also contribute to its formation.

Renal control of alkalosis. When there is an excess of alkali in the blood, as after the ingestion of bicarbonate or citrate or a vegetable diet, the urine becomes alkaline and the pH can rise as far as 7.8. Urinary ammonia diminishes and can even totally disappear. Phosphate is excreted as basic phosphate, and part of the cations are eliminated as bicarbonates, as can be seen by adding a strong acid to the urine, in which case CO_2 is released and bubbling is observed. Another renal mechanism that becomes active in alkalosis is the selective elimination of citric acid, which can be increased a hundred times after ingestion of sodium bicarbonate. There is some evidence that citric acid is formed in the kidney under these conditions.[2]

Intestinal mechanism. The part played by the intestine in the regulation of the acid-base balance is not yet well known. Certain cations, such as Ca^{++} and Mg^{++}, are excreted by the intestine, but this does not seem to be a selective excretion conditioned by the acid-base balance. For example, if an excess of $CaCl_2$ is given, Ca is eliminated in great part through the gut, and Cl^- is retained. The anion in excess diverts Na from bicarbonate and the alkali reserve dimin-

[1] Van Slyke, D. D., *et al.*, *J. Biol. Chem.*, **150**, 481, 1943.

[2] Orten, J. M., and A. H. Smith, *J. Biol. Chem.*, **128**, 101, 1939.

ishes; thus in this case ($CaCl_2$ acidosis) the intestine not only does not contribute to maintain the acid-base balance but is the cause of its disturbance by the selective excretion of Ca^{++}.

Mechanisms in the tissues. The tissues undoubtedly play a part in the regulation of the acid-base equilibrium, but the mechanism of their contribution is not yet well known. The factors that concur in the acid-base equilibrium (pH, alkali reserve) are usually estimated in the blood, which is only 7 per cent of the total body weight, and probably there are equilibriums between tissue cells and fluids similar to those existing between erythrocytes and plasma. There is evidence that the tissues are important in the regulation of acid-base balance. For example, asphyxia or the ingestion of HCl causes a decrease in the alkali reserve. In the latter case the decrease in alkali is due to acid intoxication; in the former, to the shift of base from the blood. In asphyxia, breathing mixtures of CO_2 and O_2 rapidly reestablishes the alkali reserve and improves the condition of the patient; in acid intoxication, on the contrary, this would be a dangerous procedure. According to Yandell Henderson, the displacement of base that occurs in asphyxia should not be considered as acidosis.

Other mechanisms. There are perhaps other mechanisms for regulating the acid-base balance, but nothing definite is known about them. The excretion of sweat does not play an active part, because there is no selective elimination of cations or anions through the sweat glands as through the kidneys. The adrenal glands play an important part, which will be considered when dealing with these glands, in maintaining the balance of Na and K.

METHODS FOR DETERMINING THE STATE OF THE ACID-BASE EQUILIBRIUM

These methods will be only summarily considered here.

In the blood the pH is commonly determined by the potentiometric method; less frequently, by the indicator method. The pH and the alkali reserve (CO_2 combining power of plasma) are the two factors that must be known to establish the condition of the acid-base equilibrium. The gasometric method for the determination of the alkali reserve is much simpler than the volumetric method, which uses titration of bicarbonate by adding an excess of acid and then titration of the acid with NaOH, using phenol red as indicator.

In alveolar air the percentage of CO_2 can be determined and the partial pressure calculated. The CO_2 tension of alveolar air is the same as in the blood and one of the factors in Henderson's equation is thus known. The normal concentration of CO_2 in alveolar air is 4.7 to 6.8 volumes per cent. The method is subject to error due to variations in alveolar CO_2 concentration in the lung, caused by changes in pulmonary ventilation.

In urine the acid excretion index is obtained by adding the total acidity (in cc. 0.1 *N* acid) to the urinary ammonia (in cc. 0.1 *N* NH_3) calculated in the urine excreted during 24 hr. This is an excellent way of determining the acid-base balance of the body when the kidneys are functioning normally. In a healthy adult this index varies from 0 to 1,600; higher values are a sign of excess acid production. In nephritis this method cannot be used because in this condition there can be a decrease in the alkali reserve, without a corresponding increase in urinary excretion of acid.

Bicarbonate tolerance is also an indirect method. Sodium bicarbonate is given by mouth until the urine becomes alkaline. In normal subjects 5 to 10 gm. is needed. There is no acidosis if the urine becomes alkaline with less than 0.5 gm. per kg. of body weight.

CHAPTER 32

Regulation of Respiration

THE DEPTH AND FREQUENCY of breathing, and therefore the pulmonary ventilation, are adapted in normal circumstances to the needs of the body by special regulatory mechanisms.

The respiratory muscles are under voluntary control, *i.e.*, their activity can be modified by impulses originated in the cerebral cortex, but this cortical control is limited. Thus breathing can be stopped voluntarily for a certain time, but not long enough to produce death by asphyxia. The respiratory rhythm can be modified for the emission of speech or in singing; also in strong emotional states. Nevertheless impulses from the cerebral cortex are not necessary for breathing, which continues during sleep or anesthesia and after removal of the whole cortex. The most important neural mechanism for the control of respiration is situated in the medulla. It is called the respiratory center, and it is under the influence of nervous and humoral factors.

The respiratory center has multiple effects. In the first place it coordinates the activity of the respiratory muscles so as to produce inspiration and expiration. Even the strongest voluntary effort cannot provoke inspiratory movements in one half of the thorax and expiratory movements in the other half; all the muscles taking part in inspiration (thoracic, laryngeal, dilators of the nares, and perhaps the smooth bronchial muscles) contract in a coordinated sequence. The respiratory center, under the influence of nervous and humoral factors, also regulates the frequency and strength of contraction of the respiratory muscles, and in special circumstances brings into activity the accessory respiratory muscles, thus controlling the rate and depth of breathing. This is known as the regulation of respiration.

The following aspects of the mechanism that controls breathing will be considered here: (*a*) the respiratory centers; (*b*) factors that condition the automatic rhythmic activity of the respiratory centers; (*c*) factors that regulate pulmonary ventilation.

THE RESPIRATORY CENTERS

Legallois in 1810, and Flourens in 1842, located a small region in the floor of the fourth ventricle, the destruction of which caused death due to the stopping of respiration. Flourens named this region the "*noeud vital*" (vital knot), a term which should be abandoned because it is incorrect, but which draws attention to the importance of this area for the maintenance of life.

The location of the respiratory centers has been established by experiments in which they have been destroyed or stimulated.

If the brain is sectioned in successive horizontal planes, no changes in breathing will be observed until a section has been made at the level of the rostral end of the pons and immediately caudal to the inferior colliculi. All sections above this level permit apparently normal breathing and normal respiratory responses to most nervous and chemical stimuli. Nevertheless some disturbances exist, as a section through the mid-part of the colliculi suppresses thermic polypnea (increased respiratory rate provoked by heating); and a section slightly caudal to this one suppresses reflex polypnea in light anesthesia (Fig. 152).

Sections at lower levels produce increasingly severe alterations in breathing, until it ceases completely when the section is made through the medulla at the level of the apex of the calamus scriptorius. Localized destruction and stimulation with needle electrodes, so as to affect only limited areas, have shown the exact location of

the center, or centers, in the reticular formation of the medulla, caudal to the entrance of the acoustic nerve and dorsal to the inferior olivary nuclei.

Stimulation with fine electrodes has demonstrated the existence of certain areas that provoke only inspiratory movements and of others that cause only expiratory movements.[1]

The inspiratory and expiratory areas have been accurately located by means of many experiments with needle-electrode stimulation. The two areas partially overlap, but it has been possible to establish the limits of each. In the cat, according to Pitts and his associates, the expiratory neurons are placed dorsally to the inspiratory neurons, nearer the floor of the fourth ventricle and extending farther in a cephalic direction. The inspiratory neurons are situated near the olivary nuclei, extending farther caudally. In the monkey and the dog similar areas have been located.

Although the expiratory and inspiratory neurons mingle in parts, they are functionally separated. Each one of the areas has all its neurons in close synaptic connection and acts reciprocally with the other area; thus, in localized stimulation of the inspiratory neurons, excitation spreads over the whole area and is accompanied by inhibition of the expiratory area.

Neurons on each side of the mid-line are connected by commissural fibers. A longitudinal section along the mid-line does not modify the respiratory rhythm if the vagi are intact, but if one vagus nerve is cut the respiratory rate of the denervated side diminishes; if both vagi are cut, each side of the thorax moves with an independent rhythm.

Apart from the respiratory center in the medulla, another center (or perhaps several) has been located in the upper part of the spinal cord. Respiratory movements have been observed in decapitated animals (section of the nerve centers between the medulla and the spinal cord) in certain circumstances, *e.g.*, in newborn animals, in adult animals injected with strychnine (which increases the excitability of the nerve centers), in animals maintained alive for a long period by means of artificial respiration, and in some birds. These movements provoked by spinal respiratory centers are not adequate to maintain normal breathing. The spinal centers are normally subject to the predominating influence of the medullary centers, but it is possible that when the latter are depressed the spinal centers play a more prominent part, causing disturbances in rhythm, such as periodic breathing (see Chap. 33).
FIG. 152. Diagram of brain stem showing levels at which cross sections have been made to localize the respiratory center. Between 1 and 2 the pneumotaxic center is located; the respiratory center is situated between 4 and 5. *OT*, thalamus; *P*, pineal; *G*, geniculate body; *ACQ*, anterior colliculi; *PCQ*, posterior colliculi; *Po*, pons; *M*, medulla; IV, fourth nerve; V, fifth nerve; VIII, eighth nerve. (*After Lumsden, T., J. Physiol., vol. 57, p. 153, 1923.*)

The reciprocal innervation of respiratory muscles has been demonstrated in the same way as it has in the flexor and extensor muscles of the limbs. Contraction of the inspiratory muscles is accompanied by inhibition of the expiratory muscles, and vice versa.

Rhythmic, alternating activity of the inspiratory and expiratory centers is under the influence of impulses arising in the lungs and in the pneumotaxic center (see further on). Rhythmicity of the impulses sent out by the respiratory centers has been observed by recording the action potentials in nerves of respiratory muscles, especially the phrenic nerves and the nerves of the internal and external intercostals (Adrian). In quiet breathing the inspiratory center sends out series of impulses during inspiration, which are interrupted by periods of inactivity corresponding to expiration. These discharges are of low frequency, but their rate increases in more active breathing, *e.g.*, when the CO_2 concentration in arterial blood increases.

The expiratory center is almost inactive in quiet breathing, and sends out few if any im-

[1] PITTS, R. F., H. W. MAGOUN, and S. W. RANSON, *Am. J. Physiol.*, **126**, 673, 1939.

pulses. Expiration in this condition is therefore mainly passive and produced by the elastic recoil of the thorax. When breathing is more active, *e.g.*, in muscular exercise, the expiratory center also becomes active. It then sends out rhythmic impulses alternating with the inspiratory center, and the expiratory muscles contract.

Automatic Rhythmic Activity of the Respiratory Centers

The inspiratory and expiratory centers cannot by themselves maintain a normal respiratory rhythm, because the inspiratory center discharges impulses continuously and provokes sustained inspiration (*apneusis*). This activity of the inspiratory center is periodically inhibited by impulses from the pneumotaxic center and from the lungs, and expiration can thus take place.

Pneumotaxic center. This center is situated in the midbrain, immediately caudal to the colliculi (Fig. 152). It receives impulses from the hypothalamic centers which control body temperature. If connections between the hypothalamus and the pneumotaxic center are severed in the dog, heat polypnea is suppressed. The pneumotaxic center receives impulses from the inspiratory center and stimulates the expiratory center. The latter inhibits the inspiratory center (Gray). This circuit assures alternation of inspiratory and expiratory movements. It continues to function after both vagi have been cut.

The Hering-Breuer reflex. One of the most important mechanisms that automatically regulates the respiratory rhythm is a reflex arising in the lungs. It was discovered by Hering and Breuer in 1869, and was further studied by Head in 1889. The Hering-Breuer reflex takes place as follows: Distention of the lungs, as in inspiration, originates centripetal impulses toward the respiratory centers, which inhibit inspiration in normal breathing and stimulate expiration in forced breathing. Retraction of the lungs, as in expiration, originates centripetal impulses which result in inspiration. The afferent impulses travel along fibers of the vagus nerve, the neurons of which are in the ganglion nodosum.

The rabbit is well suited for the study of this reflex because it has a fairly long slip of the diaphragm at each side of the ensiform cartilage which can be freed so as to record its movements without damage to its innervation and circulation. At the end of expiration the diaphragm begins to contract, and at the end of inspiration it relaxes. If the lungs are artificially distended beyond the normal limits, there is prolonged inhibition of the diaphragm. Conversely, if the lungs collapse and more than the normal amount of air is expelled from them, there is a prolonged tonic contraction of the diaphragm. All the other respiratory muscles respond in a similar way, *i.e.*, by relaxation of the inspiratory and contraction of the expiratory muscles when the lung is distended, and by relaxation of the expiratory and contraction of the inspiratory muscles when the lung collapses.

The Hering-Breuer reflex is originated by the mechanical distention (or retraction) of the lung, and it takes place when the lung is distended by an inert gas, such as nitrogen or hydrogen; changes in oxygen or CO_2 content play no part in this reflex. In short, at each respiratory movement (inspiration and expiration) a Hering-Breuer reflex takes place, stimuli are originated in the lung that cause the centers to discharge impulses provoking the opposite movement.

Adrian[1] has studied the Hering-Breuer reflex in the cat by registering the action potentials of the afferent fibers of the vagus. Distention (inspiration) and retraction (expiration) of the lung provoke afferent discharges in the vagus. The receptors are probably situated in the alveolar ducts. They are not sensitive to changes in the partial pressure of the gases in the lung, but respond to changes in the tension of the lung tissues. The impulses act mainly on the neurons of the inspiratory center; those originated by distention of the lung inhibit these neurons and those originated by retraction stimulate them.

In normal breathing at rest (eupnea), impulses are originated only at the end of inspiration, and they inhibit the inspiratory center. Impulses that stimulate inspiration arise only when the lung retracts (expiration) more than in normal quiet breathing; these possibly become important in dyspnea.

Section of both vagi nerves in the neck causes serious disturbance in respiratory rhythm by suppressing the Hering-Breuer reflex mechanism. Breathing is slowed down, there are deep inspirations separated by long pauses during which the thorax is held in a position halfway

[1] Adrian, E. D., *J. Physiol.*, **79**, 332, 1933.

between inspiration and expiration. About one hour after the vagi have been cut the respiratory rate increases, the mechanism of this recovery being still unknown.

If the vagi are cut above the origin of the recurrent laryngeal nerves, most of the laryngeal muscles are paralyzed and the vocal chords do not separate on inspiration, thus forming an obstacle to the passage of air. The cough reflex also disappears, owing to the section of the afferent fibers, so there is no reflex defense for the elimination of foreign bodies which fall into the larynx. This is a serious disturbance in the dog and may lead to death by infection of the lungs. The importance of the vagus in respiration varies according to the species; in guinea pigs double vagotomy is rapidly followed by death due to asphyxia caused by spasmodic contraction of the smooth muscles of the small bronchi.

An irregular respiratory rhythm is maintained after the connections between the pneumotaxic center and the medulla have been cut, if at least one vagus nerve is intact. It is also maintained after both vagi have been cut if the paths between the midbrain and the medulla are intact. If the fibers between the midbrain and the medulla and one vagus are cut, inspiration is prolonged and respiratory frequency diminishes. If then the other vagus nerve is cut, the inspiratory center no longer receives inhibitory impulses; an inspiratory spasm therefore takes place, which stops breathing (*apneusis*), and the animal dies from asphyxia. Records of action potentials in the phrenic nerve show a continuous discharge of nerve impulses, which can be inhibited, together with the inspiratory spasm, by stimulating the central end of one of the cut vagi.

There are three main types of normal breathing:[1] (*a*) eupnea, (*b*) sighing, and (*c*) panting. There are also several types of abnormal rhythm, such as Cheyne-Stokes breathing.

In eupnea (the usual type of breathing) frequency, depth, and the expiratory base line remain constant. Changes in metabolic needs modify frequency or depth, but the regularity of breathing is maintained.

Sighing is superimposed on the basic rhythm. Eupnea and sighing are observed after double vagotomy if the connections between the pons and the medulla are intact.

Panting, *e.g.*, heat polypnea in the dog, is caused by a marked increase in frequency with a decrease in depth (rapid, shallow breathing). Section of the midbrain between the colliculi severs the paths from the hypothalamus to the pneumotaxic center and suppresses heat panting.

FACTORS THAT REGULATE PULMONARY VENTILATION

Changes in the depth and frequency of breathing cause changes in pulmonary ventilation, adapting the gaseous interchange in the lungs to the requirements of the organism. Several factors play a part in regulating pulmonary ventilation. The principal ones are the sensitiveness of the respiratory center to CO_2 and the afferent impulses that come from different parts of the body.

Apart from these physiologic factors, several drugs stimulate or inhibit respiration. A drug that increases pulmonary ventilation can produce its effect by one of two mechanisms: as a direct stimulant, or indirectly by increasing the sensitiveness of the respiratory center, *i.e.*, lowering its threshold. In the first case the effect of the drug is added to that of CO_2, the physiologic stimulant; in the second case a normal CO_2 concentration in the blood acts as a stronger stimulus owing to the greater excitability of the center. It is not possible to say which of these mechanisms is the one by which respiratory stimulants act. According to Y. Henderson,[1] respiratory activity "is always the product of at least two main factors: two factors that are most conveniently denominated as (1) the strength of the stimulus and (2) the sensitivity or excitability of the respiratory center. This conception requires that carbon dioxide shall always be regarded as the sole chemical stimulus to respiration, either directly or through pH. All the other substances and conditions that increase or decrease breathing are denied as stimuli. They must rather be regarded as acting entirely by altering—either raising or lowering—the sensitivity of the respiratory center to carbon dioxide. Under this conception they are held to be stimulants, not stimuli. It is a conception that is indeed artificial and arbitrary, but extremely useful as a method of calculating

[1] HOFF, H. E., and C. G. BRECKENRIDGE, Levels of Integration of Respiratory Patterns, *J. Neurophysiol.*, **15**, 47, 1952.

[1] HENDERSON, Y., "Adventures in Respiration," Williams & Wilkins, Baltimore, 1938, p. 372.

results in a wide range of respiratory problems." Gray, however, suggests another interpretation of the facts (see page 298).

Sensitivity of the respiratory center to CO_2. The respiratory center responds up to a certain point to several factors, such as temperature and oxygen partial pressure, but undoubtedly it is most sensitive to carbon dioxide. There are, of course, individual differences, but in certain subjects an increase by 0.2 per cent in CO_2 concentration in the alveolar air doubles pulmonary ventilation. A decrease of the same magnitude causes transitory apnea. This variation in CO_2 concentration corresponds to a change in CO_2 partial pressure of 1.5 mm. Hg. The minimum (threshold) variation in CO_2 partial pressure that modifies breathing in man is approximately 0.075 mm. Hg. CO_2 exerts its influence on the centers, as is proved by experiments in animals in which the vasosensory areas (see page 295) have been denervated. This can also be demonstrated by cross-circulation experiments, in which the head of a dog *A* receives its blood supply from a second dog *B*. If the latter breathes air in which the CO_2 concentration is high, pulmonary ventilation increases in dog *A*.

The effect of CO_2 increases with its concentration in the alveolar air up to a maximum at 9 per cent; at higher concentrations CO_2 depresses the respiratory center.

The pH of the blood depends on the ratio of free CO_2 to bicarbonate, as is shown in Henderson's and Hasselbalch's equations. The injection of acid increases pulmonary ventilation, so the problem of whether CO_2 acts directly as a stimulus of the respiratory center or by modifying the hydrogen ion concentration, which would be the direct stimulus, has been the subject of much discussion.

At first this question could not be answered. Some workers (Haldane, Winterstein, etc.) considered the hydrogen ion concentration to be the physiologic stimulus of the respiratory center; others (Collip, etc.) thought it was the HCO_2^-. In certain circumstances pulmonary ventilation and the acidity of the blood do not vary simultaneously. Gesell supposed that this was due to several factors; for instance, CO_2 is more diffusible than H^+, and acid products may arise in the course of the cellular metabolism of the respiratory center. If CO_2 concentration in the blood increases without a change in the free CO_2–bicarbonate ratio (Henderson's equation), the pH does not vary, but there may be an increase in acidity in the tissues because of the greater diffusibility of dissolved CO_2. This can be demonstrated in several ways; *e.g.*, the flowers of *Symphytum peregrinum*[1] are blue in a neutral or alkaline medium and red in acid medium. Submerged in acid water of pH 5 to 6, they remain blue, but in a solution of carbonic acid and sodium bicarbonate of pH 7.4, they change to red, because CO_2 diffuses rapidly into the cells and acidifies them.

Gesell measured the variations in the pH of the cells of the respiratory center by means of electrodes placed in the cerebrospinal fluid, thus obtaining a continuous record of the changes taking place; simultaneously he obtained a record of pH variations in the blood. He concluded that stimulation of the respiratory center depends on changes in acidity within the center, changes which in some circumstances do not coincide with those occurring in the blood. These experiments demonstrate the importance of intracellular changes but do not solve the problem of whether cH^+ or H_2CO_3 is the stimulus of the respiratory center.

More recent work seems to show that H_2CO_3 has a specific effect on the respiratory center, independent of its effect on cH^+. The following facts, mainly due to research done by Krogh, are the principal arguments that support this statement: (*a*) prolonged breathing of air with CO_2 provokes intense hyperpnea, while there are insignificant changes in blood pH; (*b*) ingestion of ammonium chloride, an acidogenous salt, acidifies the blood but causes little or no hyperpnea. For example, breathing air with 4 per cent CO_2 increased pulmonary ventilation by 10 liters per min., accompanied by a decrease in pH of 0.04 to 0.045; ingestion of ammonium chloride decreased blood pH by 0.08 and increased pulmonary ventilation by only 0.3 liters per min. On the other hand cases of acidosis with hyperpnea have been observed, in which there is acapnia, and hyperpnea persists even when the CO_2 partial pressure in alveolar air is only one-half or one-quarter the normal value. It is not possible to discard the suggestion that in these cases hyperpnea is due to a reflex originated in the chemoreceptors of the vasosensory areas.

Another striking demonstration of the specific effect of CO_2 has been given by perfusing the medulla with blood in which constant acidity

[1] JACOBS, M. H., *Am. J. Physiol.*, 53, 457, 1920.

is maintained by CO_2 or by HCl; in the first case pulmonary ventilation increases to 3,069 per cent, while in the second it increases to only 128 per cent (Hooker *et al.*). Comroe, by injecting different solutions into the medulla, was able to stimulate respiration with buffer systems of bicarbonate, but only in a few cases could he obtain similar results with solutions of lactic acid or HCl.

The weight of the evidence is therefore in favor of the idea that stimulation of the respiratory center is due to a specific or preponderant effect of carbonic acid acting within the center, and not to changes in hydrogen ion concentration conditioned by the ratio of dissolved CO_2 to fixed CO_2.

The part played by changes in oxygen tension. The respiratory center is very sensitive to lack of oxygen; anoxia of a certain intensity and duration depresses the center and, if it lasts for more than a few minutes, may produce irreversible damage. Nevertheless when the oxygen partial pressure decreases, at first there is an increase in pulmonary ventilation, which may be fairly prolonged if anoxia is not too intense. This is due to an increase in the excitability of the respiratory center caused by impulses arising in the chemical receptors of the vasosensory areas (see further on). A fall in oxygen partial pressure increases primarily the depth of breathing and, in a lesser degree, the respiratory rate. These changes are less marked than those produced by increase in CO_2, but they are sufficient to cause a significant increase in pulmonary ventilation.

There are considerable individual variations in the minimum (threshold) decrease in oxygen tension that can modify pulmonary ventilation. Expressed as percentages of oxygen at sea-level pressure, significant changes begin in most subjects when the inspired air contains only 13 per cent oxygen, but some normal individuals respond with increased breathing when oxygen in the air drops to 18 per cent.

The symptoms provoked by a decrease in oxygen tension become severer as anoxia increases. A drop from 21 to 18 per cent (159 to 137 mm. Hg oxygen partial pressure) does not cause any disturbance in respiration. Between 16 and 12 per cent (121 to 91 mm.) pulmonary ventilation increases, there is a quicker pulse rate, incoordinated movements appear, and muscular efficiency diminishes. In an atmosphere of 12 per cent oxygen, a candle does not burn. Between 14 and 9 per cent (106 to 68 mm.) the respiratory and pulse rates increase even more. There is periodic (Cheyne-Stokes) breathing, cyanosis, vomiting, asthenia, and fatigue. Errors are committed when doing simple arithmetical calculations, and there are changes in behavior, the subject sometimes reacting violently. Between 10 and 6 per cent (76 to 45 mm.) the subject is excited, and there is intense cyanosis. The electrocardiogram shows alterations; the PR and RT intervals decrease, and the amplitude of T diminishes. Blood pressure falls, syncope may occur, and sometimes the subject becomes comatose. Respiration is at first deep and then becomes shallow and frequent, ending in inspiratory spasm. A decrease in oxygen percentage (or its equivalent partial pressure) of this magnitude is tolerated for only a very short time. A drop to 5 or 3 per cent (38 to 23 mm.) is rapidly fatal.

Accidents observed in rarefied air are due to the decrease in oxygen partial pressure and not to the fall in total pressure. Paul Bert observed many years ago that the total pressure can fall considerably without causing accidents if the subject breathes pure oxygen. Further details will be given when considering mountain sickness (see Chap. 33).

Vasosensory respiratory reflexes. The importance of vasosensory areas in the control of circulation has already been discussed (see Chaps. 17 and 20). The main vasosensory areas are situated in the aortic arch, innervated by the cardioaortic nerve, and the carotid sinuses at the bifurcation of the common carotid, innervated by the sinus nerves of Hering. There are two types of receptors in these areas; one type is sensitive to changes in arterial blood pressure (pressoreceptors), the other to changes in the chemical composition of the blood (chemoreceptors). The pressoreceptors are found in the wall of the arteries, and the chemoreceptors in the aortic and carotid bodies.

Changes in arterial blood pressure and in the chemical composition of the blood stimulate these receptors and originate impulses which travel along the cardioaortic and sinus nerves. These impulses modify the excitability of the respiratory centers and cause respiratory reflexes which are suppressed by total denervation of these areas. The part played by the vasosensory areas in the regulation of breathing has been

studied in experiments of total or partial denervation of the areas, destruction of the aortic and carotid bodies, perfusion of the carotid sinus with blood of controlled chemical composition at controlled pressure before and after cutting the sinus nerve or extirpating the carotid body, etc. A long series of important experiments, many of them by Heymans and his associates, have accumulated many facts confirming some classical ideas and adding new ones on the regulation of circulation and respiration.

The influence of pressoreceptors on respiration. A sudden increase in arterial blood pressure inhibits respiration and may cause transitory apnea. This is commonly seen when injecting adrenaline into dogs. Hypotension, such as is caused by inhalation of amyl nitrite, accelerates breathing. The reflex nature of these responses is demonstrated by the following experiment: The carotid sinus of a dog is perfused by anastomosis of the common carotid with the artery of a second dog. The blood pressure is increased or decreased in the second dog, and changes in respiratory rate are observed in the perfused animal. Denervation of the perfused carotid sinus suppresses the effect of variations in blood pressure on respiration.

Pressoreceptors are more important for the reflex control of circulation than of respiration. Thus section of both cardioaortic and sinus nerves causes prolonged permanent hypertension, but only transitory hyperpnea, and in some experiments no significant change in breathing has been observed. Pressor changes in the sinus provoke reflex changes in arterial blood pressure, which are proportionate to the sinus variation and last as long as the sinus pressure does not alter. The respiratory response, on the other hand, is not sustained; there is only transitory apnea or hyperpnea when the sinus pressure suddenly rises or falls.

The influence of chemoreceptors on respiration. Receptors in the aortic and carotid bodies which respond to changes in the chemical composition of the blood play a relatively small part in the regulation of circulation, but they are of considerable importance in the control of respiration. These chemoreceptors are stimulated by a decrease in oxygen tension, by an increase in hydrogen ion concentration or carbonic acid, and by nicotine, cyanide, H_2S, and other drugs.

The principal physiologic stimulus is the decrease in the oxygen partial pressure of the blood. Sensitiveness of chemoreceptors to small changes in oxygen partial pressure can be demonstrated in animals if care is taken to avoid depression by anesthetics. Decerebrated cats are 100 times more sensitive than cats anesthetized with chloralose, and 10,000 times more sensitive than dogs under the same anesthetic.[1] Records of action potentials in Hering's nerve show that chemoreceptors begin to discharge when oxyhemoglobin is 96 per cent saturated. Activity increases as oxygen saturation of hemoglobin diminishes, almost in linear relation, with a maximum at 15 per cent oxyhemoglobin. The decrease in oxygen partial pressure acts as a stimulus; anemic anoxia does not stimulate the chemoreceptors. Owing to their high sensitiveness to decreases in oxygen partial pressures, chemoreceptors should be considered as part of the mechanism controlling oxygen equilibrium in arterial blood in normal conditions, and not simply as an emergency mechanism, as experiments on anesthetized animals seemed to indicate.

Sensitiveness to an increase in hydrogen ion concentration or CO_2 has been demonstrated in perfusion experiments in which the carotid body and sinus nerves are intact. In physiologic conditions these stimuli are not of much importance, since a change of 0.1 in pH is needed to produce the minimum (threshold) response and variations of this magnitude seldom occur in normal subjects.

The chemoreceptors are not very sensitive to changes in arterial CO_2 partial pressure, which must be of the order of 10 mm. to produce effects. The respiratory centers, on the other hand, respond to changes in arterial CO_2 partial pressure of 0.075 mm. Hg. Therefore CO_2 cannot be considered as the normal stimulus of the chemoreceptors.

A salient feature of the chemoreceptors is their great resistance compared with that of the respiratory centers. Thus anoxia of a certain intensity and duration depresses the respiratory center, but does not disturb the chemoreceptors. This is well demonstrated by perfusing the carotid sinus with fluid free from oxygen. Hyperpnea is provoked and sustained while the perfusion lasts; it ceases immediately on adding oxygen to the perfusion fluid. Resistance of the chemoreceptors to lack of oxygen is perhaps an

[1] Alvarez-Buylla, R., *Arch. Inst. cardiol. México,* **21,** 724, 1951.

important factor in maintaining respiration in serious anoxia. This chemical reflex mechanism is the *ultimum moriens* in the control of respiration (Comroe and Schmidt).

Chemoreceptors are also sensitive to other stimuli, *e.g.*, changes in temperature, but as these must be of great magnitude to reach the threshold, they are not of physiologic importance. Of more importance is the effect of drugs. Nicotine, lobeline, cyanides, and H_2S in adequate doses stimulate the chemoreceptors and produce an increase in pulmonary ventilation. The following facts are evidence of this statement:

1. Complete denervation of the receptors by section of both cardioaortic and sinus nerves suppresses the respiratory effects of these drugs.
2. Perfusion of the carotid sinus of a dog with fluid containing one of these drugs has the same effect as the injection of the drug into the general circulation.
3. Very small doses of the drugs, which have no effect when injected into the general circulation, produce a respiratory response when injected into the aorta, thus reaching the chemoreceptors in higher concentration.
4. Injection of the drugs provokes the appearance of action potentials in the sensory nerves of the receptors, showing that these have been stimulated.

Hyperpnea in muscular exercise. Muscular exercise causes an increase in pulmonary ventilation, which has been attributed to the effect of CO_2, owing to the exquisite sensitivity of the respiratory center to minute increases in arterial CO_2 tension. Evidence recently obtained shows that other factors are even more important.

Barcroft and Margaria observed that the maximum pulmonary ventilation that could be provoked by breathing air mixtures with CO_2 was of 50 to 60 liters per minute. On the other hand, violent muscular exercise could increase pulmonary ventilation to twice this figure, although the sensation of distress in breathing was not so marked as when breathing the CO_2 mixtures.

In muscular exercise, changes in alveolar CO_2 tension are not parallel to changes in pulmonary ventilation. CO_2 tension increases in moderate exercise and usually diminishes as the intensity of the exercise increases, being generally below normal in violent exercise. Moreover, hyperventilation increases before there is any significant increase in CO_2 output.

Lactic acid, released in the course of muscular contraction, has been considered the additional factor necessary to produce this hyperpnea; but in moderate exercise there is a threefold to fourfold increase in pulmonary ventilation without any significant increase in blood lactic acid.

It is generally accepted that hyperpnea observed in exercise is due to reflexes arising in the muscles, which increase the excitability of the respiratory center. There is some experimental evidence in support of this assertion. Electrical stimulation of the muscles, or even passive movement of a limb, increases pulmonary ventilation in the dog. Occlusion of the blood vessels of the limb does not suppress this response, but denervation or anesthesia of the nerves with cocaine abolishes it. Whether or not metabolic products originated by muscular contraction act locally is still under discussion.

Reflexes originated in the large veins and auricles, similar to the reflex acceleration of the heart rate provoked by distention of these structures (Bainbridge's reflex), have also been considered factors in the mechanism of the hyperpnea of muscular exercise. Hyperthermia stimulates breathing, but it cannot be a factor in the initial hyperventilation of exercise, because the rise in temperature occurs much later. Perhaps adrenaline, which stimulates respiration in doses too small to cause a rise in blood pressure, also concurs in the production of this hyperpnea.

In summary, experimental evidence has shown that hyperpnea of exercise is caused mainly by a reflex increase in the sensitivity of the respiratory center. An increase in CO_2 or lactic acid during the first stages is of secondary importance and may not take place although hyperpnea occurs.

Other factors that act on respiration. Pi-Suñer has reported a specific sensitivity of the lung to a local increase in CO_2, but there is no definite proof that this mechanism acts within the normal limits of variation of CO_2 partial pressure.

Stimulation of the trigeminal nerve endings in the nasal mucosa by inhalation of an irritant gas (Cl_2 or NH_3) stops respiration. Initial apnea in ether anesthesia is due to the same cause; it ceases when sufficient CO_2 has accumulated to overcome the inhibitory reflex impulses. As anesthesia progresses the nerve centers lose their sensitivity and the apneic pauses disappear.

Irritation of the nasal mucosa with weaker stimuli provokes sneezing.

Coughing is a reflex originated in the pharynx (innervated by the glossopharyngeal), larynx, trachea, or bronchi (innervated by the vagus). The most sensitive area is situated in the larynx above the vocal chords. Vagotomy above the recurrent laryngeal nerves suppresses the coughing reflex by anesthetizing the mucosa where it originates. In the dog this defensive reaction is of considerable importance in avoiding the entrance of foreign bodies into the lungs; hence the seriousness of vagotomy in this species.

Coughing consists of a deep inspiration followed by a sudden sharp expiratory movement, keeping the glottis closed until it is overcome by the pressure in the lung. Thus a strong current of air is originated, which carries away the stimulating agent (mucus, foreign bodies, etc.). Sneezing is caused by a similar mechanism. Coughing can be performed voluntarily, but once deep inspiration has started as a result of a stimulus of sufficient strength, it is very difficult to inhibit it voluntarily; perhaps the Hering-Breuer reflex plays a part in the expiratory phase of coughing. Coughing can be diminished in bronchitis by shallow breathing; thus the probability of a strong expiratory movement, which may follow a deep inspiration, is reduced.

Anesthesia and other conditions that depress the nerve centers also depress the cough reflex and increase the danger of pulmonary infection due to retention of secretions and foreign bodies.

Intense irritation of the larynx provokes spasm of the glottis, which can be considerably dangerous in children.

Deglutition reflexly inhibits respiration.

Painful sensations and emotions (fear, rage, etc.) increase the respiratory rate and pulmonary ventilation. The influence of the cortex on respiration is also evident in the spasmodically interrupted breathing of sobbing and laughter, but the mechanism of this cortical effect is still unknown.

Respiratory rhythm, frequency, and depth are the result of the integration of all the factors that concur in the adaptation of pulmonary ventilation to the needs of the organism. As Comroe[1] has very aptly expressed it, "respiration is controlled not by reflexes alone, not by chemical stimulation of the medulla alone, but by the proper interaction of both factors. No reflex, no matter how strong, can stimulate respiration if the arterial CO_2 tension has been lowered abnormally; no chemical stimulant, no matter how great, can produce rhythmic breathing if the medullary centers have been completely cut off from all nervous influences."

[1] Comroe, J. H., *Physiol. Rev.*, 24, 333, 1944.

The multiple-factor theory of the control of respiratory ventilation. Respiration is controlled by complex mechanisms and, according to Gray, there is no single "true" stimulus. Changes in the pH and partial pressures of O_2 and CO_2 in blood vary according to the cause which has provoked hyperpnea (Table 29), a fact that has led Gray to propose a multiple-factor theory of respiratory control.

Table 29. Maximum Pulmonary Ventilation in Four Types of Hyperpnea

Condition	*Maximum ventilation, liters/min.*	*Changes in arterial blood*		
		P.p. O_2	*P.p. CO_2*	*pH*
Anoxia	12	↓	↓	↑
Breathing CO_2	70	↑	↑	↓
Metabolic acidosis	35	↑	↓	↓
Exercise (moderate)	50	0	0	0
Exercise (violent)	100	0	↓	↓

Source: Gray, J. S., "Pulmonary Ventilation and Its Physiological Regulation," Charles C Thomas, Springfield, Ill., 1950.

Functional integration of the respiratory centers (inspiratory and expiratory) with the pneumotaxic center and the Hering-Breuer reflexes has to do with the control of periodicity and depth of breathing, but not with direct control of the respiratory minute volume. Other factors also take part in the regulation of pulmonary ventilation, though finally the same centers and paths come into play.

Oxygen and CO_2 tensions and the pH in the blood can vary in different ways, according to the cause of hyperventilation; therefore there cannot be only one factor of adaptation. The multiple-factor theory of Gray is based on three main principles:

1. The multiple-factor principle states that a number of factors exert independent effects upon respiratory ventilation. These factors are (*a*) changes in the pH and CO_2 acting on central (medullary) chemoreceptors; (*b*) changes in O_2 tension acting on peripheral

chemoreceptors; (*c*) afferent impulses arising in the course of muscular exercise; (*d*) pressor-receptor reflexes arising in the large arteries and veins; (*e*) thermic reflexes arising in thermoreceptors in the skin sensitive to changes in the temperature of the environment, and in the hypothalamus sensitive to changes in the temperature of the blood; (*f*) afferent impulses from pain receptors and psychic influences. The most important are the chemical changes (pH and CO_2 and O_2 tensions) and muscular reflexes.

2. The interdependence principle states that a change in any one of the respiratory factors usually brings about changes in one or more of the other factors.
3. The algebraic-summation principle states that the actual ventilation is defined as the algebraic sum of the partial effects of the separate agents.

CHAPTER 33

Disturbances in Respiratory Function

PULMONARY RESPIRATION is usually automatic and does not intrude into the conscious sphere; but in contrast to other visceral functions, it can enter consciousness if the attention is directed toward it, and it can, to a certain extent, be modified at will. Normal automatic respiration is called eupnea.

DYSPNEA

Dyspnea literally means difficult breathing. It involves an objective factor, the active participation of the accessory inspiratory and expiratory muscles, and a subjective factor, the sensation of effort in breathing. According to Meakins the second factor is the more significant; he defines dyspnea as "the consciousness of the necessity for increased respiratory effort." The subjective factor, however, is absent in certain cases of dyspnea, *e.g.*, in anesthetized or comatose patients.

"Hyperpnea" means an increase in pulmonary ventilation, and "tachypnea," increased respiratory frequency. These conditions should be distinguished from dyspnea, although they can be found in dyspneic subjects, because they can exist without dyspnea, *e.g.*, during moderate exercise.

The change from eupnea to dyspnea takes place gradually. Usually there is a close connection between vital capacity and the ease with which dyspnea occurs. As the vital capacity diminishes, liability to dyspnea increases, but vital capacity is not the only factor conditioning dyspnea.

Dyspnea can be the result of many causes, but there are three main ones: (*a*) oxygen insufficiency; (*b*) CO_2 excess; (*c*) direct or reflex hyperexcitability of the respiratory center. Usually the three are combined. The principal functional disturbances that provoke dyspnea are (*a*) insufficient oxygenation of the blood as it passes through the lungs; (*b*) acidosis; (*c*) increased metabolic rate; (*d*) lesions in the vicinity of the respiratory center; (*e*) emotional and nervous excitation; (*f*) hyperexcitability of the Hering-Breuer reflex.

Insufficient oxygenation of the blood.[1] Insufficient oxygenation of the blood stimulates the respiratory center by reflexes arising in the chemoreceptors in the aortic and carotid bodies. Lack of oxygen in the blood may be due to (*a*) disturbances in the lung; (*b*) low oxygen partial pressure in the inspired air; (*c*) circulatory disturbances; (*d*) deficiency in the oxygen-carrying capacity of the blood due to lack or alteration of hemoglobin.

Disturbances in the lung. Gaseous interchange in the lungs may be hindered by obstruction of the larynx, trachea, or bronchi; by spasm of the smooth muscles of the bronchi (asthma); by the presence of fluid in the alveoli (alveolitis, edema, pneumonia); by a decrease in the respiratory surface caused by pulmonary collapse (pneumothorax), compression of the lung (pleural effusion), inflammatory processes (pneumonia), obstruction of a pulmonary blood vessel (infarct), etc.; by thickening of the pulmonary epithelium; by loss of elasticity of the pulmonary tissue (emphysema); by partial paralysis of the respiratory muscles. When the respiratory sur-

[1] The causes of insufficient oxygenation of the blood will be studied in detail in the section on anoxia. In order to avoid repetition they will only be mentioned here.

face is diminished and in cases of emphysema, the Hering-Breuer reflex is also exaggerated and rapid shallow breathing (tachypnea) results.

Low oxygen partial pressure in the inspired air. This occurs at high altitudes and in mines and submarines; also in the course of anesthesia with gases of relatively weak effect such as nitrous oxide and ethylene, which must therefore be given in concentrations of 80 per cent and even more. These gases should be given mixed with pure oxygen, so as to maintain an adequate oxygen partial pressure.

Circulatory disturbances. Among these the following can be mentioned: short circuits within the pulmonary circulation or the heart (congenital malformation); pulmonary congestion due to heart insufficiency; sclerosis of the pulmonary arteries; and circulatory collapse (which also causes retention of CO_2).

Deficiency in the oxygen-carrying capacity of the blood. This occurs in cases of severe anemia, or when hemoglobin is transformed into carboxyhemoglobin (carbon monoxide intoxication) or into methemoglobin or sulfhemoglobin.

Acidosis. Acidosis is due to the increase of free CO_2 in relation to fixed CO_2 (bicarbonate), and this results in stimulation of the respiratory center. This cause of dyspnea is frequently combined with others. Acidotic dyspnea is observed after inhalation of CO_2; after ingestion of acidogenous salts, such as calcium or ammonium chloride; and in endogenous uncompensated acidosis (diabetic coma, uremia).

Increased metabolic rate. Exercise does not provoke dyspnea in a normal subject unless it is fairly strenuous. The important factor in this case seems to be reflex stimulation of the respiratory center by impulses arising in the active muscles; lack of oxygen and accumulation of CO_2 apparently play a secondary part. Moderate exercise causes dyspnea in subjects with certain chronic cardiac diseases (cardiac dyspnea).

Lesions in the respiratory center. Many disturbances of the brain centers (encephalitis, brain tumors, cerebral hemorrhage, edema, etc.) provoke dyspnea. Intracranial pressure is increased in these cases and probably there is an insufficient blood supply to the respiratory center, which causes local acidosis, this being the main factor in the abnormal stimulation of the center. Certain drugs (caffeine, strychnine, atropine, etc.), acting directly on the center, also provoke dyspnea.

Emotional and nervous excitation. Psychically unstable individuals (neurotics, hysterical persons) sometimes have attacks of dyspnea, similar to those accompanying strong emotion. In these cases cortical excitation probably spreads down to the respiratory center.

Hyperexcitability of the Hering-Breuer reflex. Reflex dyspnea. In certain cases the Hering-Breuer reflex is abnormally strong, and causes rapid shallow breathing and consequently insufficient pulmonary ventilation, thus providing another cause of dyspnea. An exaggerated Hering-Breuer reflex is observed when the respiratory surface of the lung is considerably reduced, as in pneumothorax, atelectasis, pulmonary embolism, etc. The importance of the reflex can be demonstrated by cutting both vagi, an operation which immediately suppresses rapid shallow breathing. Hypersensitiveness of the pulmonary stretch receptors seems to be the cause of this type of dyspnea.

Cardiac asthma and orthopnea. Cardiac dyspnea is observed in certain cases of heart disease in which there is congestion (and sometimes edema) of the lung. The decrease in vital capacity, and probably in pulmonary distensibility, diminishes the amplitude of the respiratory movements. The Hering-Breuer reflex is exaggerated, and shallow breathing causes insufficient oxygenation of the blood. Dyspnea is the result of all these factors. In certain forms of severe cardiac insufficiency, especially if there is hypertension, paroxysmal attacks of dyspnea occur, usually during the night; this is known as cardiac asthma. Morphine diminishes the severity of the attacks of cardiac asthma, because this drug depresses the respiratory center.

Dyspnea increases when the patient lies down and diminishes when the thorax is in a vertical position. This is known as orthopnea. The improvement in breathing observed in this position has been interpreted as due to the following mechanism: when the thorax is in the orthopneic position (*i.e.*, vertical) the abdominal viscera do not press against the diaphragm, and the negative pleural pressure increases; this causes pulmonary congestion to diminish. The distensibility of the lung and vital capacity increases; this causes the Hering-Breuer reflex to diminish; circulation improves, the pressure of the cerebrospinal fluid diminishes, and the blood supply to the respiratory center also improves.

APNEA

Apnea literally means absence of breathing, but the term is used to signify temporary suspension of breathing. Apnea can be provoked by several causes, the most common being acapnia, *i.e.*, a fall in the CO_2 concentration of the plasma due to hyperventilation (Fig. 153).

Fig. 153. Pneumogram of a dog. Chloralose anesthesia. The arrow marks intravenous injection of 0.1 mg. nicotine per kg. There is hyperpnea followed by apnea. Time in minutes.

Hyperventilation, obtained by forced breathing during 2 min., provokes a series of responses due to the alkalinization of the blood. One of these is that the need to breathe is not felt for several minutes while CO_2 accumulates and again reaches a certain concentration. This fact is used by divers to prolong the time they can remain under water. If hyperventilation is carried out in an atmosphere of pure oxygen, apnea can be prolonged for an even longer time.

Apnea due to acapnia can be provoked experimentally in animals, and it has been amply demonstrated that it is due to a decrease in CO_2 concentration and not to a decrease in the excitability of the respiratory center or to a reflex. Hyperventilation with air or oxygen containing an adequate CO_2 concentration is not followed by apnea. Section of both vagi, so as to suppress the Hering-Breuer reflex, does not prevent apnea after hyperventilation. The importance of CO_2 concentration has also been demonstrated in crossed-circulation experiments. The head of a dog *A* is supplied with blood from the body of a second dog *B*, and the body of *A* supplies the head of *B*. Hyperventilation of *B* causes apnea in *A*; and the accumulation of CO_2 (hypercapnia) in *A*, due to the stopping of breathing, causes hyperventilation in *B*. Perfusion of an isolated head gives even more spectacular results, because the only blood supply to the perfused head comes from the perfusing animal, while in the crossed-circulation experiments some blood reaches the head from the body of the same animal by way of the arteries in the spinal canal. Perfusion of the head with hypercapnic blood causes ample and rapid movements of the alae nasi, and if asphyxia is pronounced, gasping movements of the jaw. Perfusion with acapnic blood causes the movements of the alae nasi to cease.

Apnea due to hyperventilation is of practical importance in general anesthesia, especially in ether anesthesia. During the initial phase there is hyperexcitability of the respiratory center and hyperventilation occurs. Later, as anesthesia progresses, the excitability of the respiratory center diminishes and returns to normal or below. Acapnia provoked by the initial hyperventilation is more marked as the sensitiveness of the respiratory center is depressed. Anoxia can thus be provoked, and precautions should be taken to avoid it. This can be done by adding 5 to 8 per cent CO_2 and oxygen to the anesthetic gases. Usually the patient is made to rebreathe his own expired air, which contains CO_2.

During apnea due to acapnia there are other symptoms of alkalosis: dizziness, sometimes vomiting, and signs of neuromuscular hyperexcitability, such as exaggeration of reflexes and

spontaneous muscular contractions, *i.e.*, tetany due to alkalosis.

Apnea is also caused by a decrease in the excitability of the respiratory center. Thus intravenous injection of a sufficient dose of morphine into a dog produces apnea, which lasts until CO_2 accumulates and reaches a high enough concentration to stimulate the depressed respiratory center.

Sudden arterial hypertension causes transitory apnea due to a reflex initiated in the vasosensory areas.
FIG. 154. Periodic breathing. Pneumogram of subject with Cheyne-Stokes breathing due to hyperpnea caused by anoxia. 1, a gas mixture containing only 9.84 per cent oxygen is breathed, evoking hyperpnea; 2, the subject breathes air. Time in 10 sec. (*Haldane, J. S., and J. G. Priestley, "Respiration," Oxford, New York, 1935, p. 196.*)

PERIODIC BREATHING

Periodic breathing is an involuntary disturbance in respiratory rhythm. It can be of several types, but the most common is known as Cheyne-Stokes breathing. This consists in the regular alternation of periods of breathing separated by periods of apnea. Breathing commences by shallow movements, which gradually increase in amplitude and sometimes become dyspneic. Respiratory movements then gradually decrease in amplitude, and eventually cease. After a period of apnea another cycle commences. The duration of the periods of apnea and breathing varies considerably in different cases (Fig. 154).

There are other types of periodic breathing. Thus in Biot's breathing, the periods of breathing begin and end suddenly, without the gradual increase and decrease in the amplitude of the respiratory movements typical of Cheyne-Stokes breathing; there is also considerable irregularity in the duration of the different periods. Biot's breathing is observed in meningitis and has a more serious significance than Cheyne-Stokes breathing.

The periods in Cheyne-Stokes breathing are nearly always accompanied by periodic variations in arterial blood pressure, which falls during apnea, and rises during the period of breathing. Sometimes patients with Cheyne-Stokes breathing lose consciousness during the apneic periods.

Cheyne-Stokes breathing occurs in many different circumstances. It is sometimes seen in normal infants, during sleep, especially in premature babies; it is rarely observed in normal adults. It is a frequent occurrence in the course of adaptation to high altitudes, especially during sleep. It is also observed after apnea caused by hyperpnea. It is normal in aquatic mammals (seals, etc.),[1] and in hibernating animals during the winter sleep.

Cheyne-Stokes breathing may be a sign of anoxia due to cardiac decompensation or of pulmonary origin (pneumonia, etc.), of toxic depression of the respiratory center (morphine, anesthesia), of uremia, or of lesions of the nerve centers (endocranial hypertension).

The fundamental factor in periodic breathing is anoxia of the medullary centers; probably there is also depression of the respiratory and other brain centers. There are still many unexplained points in the mechanism of periodic breathing. The following interpretation of Cheyne-Stokes breathing has been widely accepted: Anoxia diminishes the excitability of the respiratory center and provokes apnea. This increases anoxia sufficiently to stimulate the chemoreceptors in the carotid and aortic bodies, and the excitability of the center is increased reflexly; during the apneic period CO_2 is accumulated and reaches a concentration high enough to stimulate the respiratory center. Respiration is reestablished; therefore anoxia and CO_2 concentration diminish, and again apnea occurs. The breathing of oxygen or air with CO_2 usually suppresses periodic breathing.

Other centers besides the respiratory center play a part in the establishment of periodic breathing. This is evident by the greater ease with which this type of breathing takes place during sleep or unconsciousness, and under the effects of drugs that depress the central nervous

[1] SWINDLE, P. F., *Am. J. Physiol.*, **79**, 188, 1926.

system. Periodic breathing is difficult to provoke in the dog, but it is more easily established after decerebration. Swindle maintains that there are spinal centers that emit periodic respiratory impulses, normally controlled by the respiratory center in the medulla. In the newborn the medulla has not yet acquired complete control over the spinal centers; hence the frequent occurrence of Cheyne-Stokes breathing in infants. The importance of other nerve centers and the mechanism by which they take part in the production of periodic breathing are not yet well understood.

ANOXIA

When there is not a sufficient amount of oxygen to satisfy the normal requirements of cells, a state of anoxia is established.

Anoxemia literally means lack of oxygen in the blood. Anoxia has a wider significance, because in some cases oxygen insufficiency in the tissues, or the disturbance in the utilization of oxygen, is not due to lack of oxygen in the blood. "Hypoxia" would be a more correct term, as vertebrates cannot survive total lack of oxygen for more than a very few minutes; but "anoxia" is currently used and it should be understood to signify not complete absence of oxygen but oxygen insufficiency. The use of a word with a meaning different from its original or literal meaning often becomes widely accepted; *e.g.*, "anemia," which literally means absence of blood, and "oxygen," which means a generator of acids, are words commonly used with a somewhat different significance. When a term is thus in current use, it should be accepted, provided that the new meaning is well defined.

Anoxia is frequently accompanied by changes in CO_2 concentration and alkali reserve. Special terms are used in these cases. "Acapnia" (Greek α, negative prefix, and *καπνος*, smoke) signifies a decrease in the CO_2 concentration of the blood. "Hypocapnia" has the same meaning; "hypercapnia" signifies an increase in blood CO_2 concentration. "Acarbia" ("hypocarbia") and "hypercarbia" mean respectively decrease and increase in alkali reserve. "Asphyxia" literally means "not to throb" (Greek α, negative prefix, and *σφυξειν*, to throb). It is frequently used incorrectly as a synonym for "anoxia"; it means lack of oxygen plus retention of CO_2, *i.e.*, anoxia plus hypercapnia.

Classification of anoxia. There are four types of anoxia, according to the origin of the disturbance: (*a*) anoxic anoxia, due to insufficient oxygenation of the blood in the lungs; (*b*) anemic anoxia, due to a lowered oxygen capacity of the blood; (*c*) stagnant anoxia, due to circulatory disturbances that prevent the rapid circulation of oxygenated blood in the capillaries; (*d*) histotoxic anoxia, due to poisoning of the oxidizing mechanisms of the tissues. These four types will be considered first; then a more detailed study will be made of certain practically important forms of anoxia.

Anoxic anoxia. Venous blood normally retains a considerable amount of oxygen (see Chap. 27). In a normal subject at rest arterial blood loses only 6 volumes per cent oxygen on passing through the capillaries; venous blood has 14 volumes per cent oxygen. The important factor in this exchange of O_2 between HbO_2 and the tissues is not the volume of gas but the difference in the partial pressures. The oxygen tension in arterial blood is 100 mm. Hg; in venous blood it is 37 mm. Hg. Venous blood has a volume of oxygen amply sufficient for all the needs of a resting organism, but it is at a low partial pressure so it is not easily given up to the tissues.

Oxygen tension is not the only factor conditioning its passage from the lung to the blood and from the blood to the tissues; an increase in CO_2 concentration favors the release of oxygen from hemoglobin. This factor has special importance in anoxia at high altitudes.

At the normal oxygen tension of arterial blood (100 mm. Hg) 95 per cent of the hemoglobin is in the state of HbO_2. When the O_2 tension and the percentage of HbO_2 are below these figures, there will be anoxic anoxia.

Anoxic anoxia is due to the following causes:

1. *Low oxygen tension in inspired air.*
   - *a.* Decrease in total pressure such as occurs at high altitudes, in decompression chambers for reproducing conditions in high altitudes, etc.
   - *b.* Respiration of inert gases.
   - *c.* Breathing in a confined space, such as that of submarines, mines, etc., in which oxygen is consumed; increase in the dead space; breathing in a closed circuit, as in administration of anesthesia with ethylene or nitrous oxide, which must be breathed in high concentration.

2. *Disturbances in pulmonary exchange of gases; hypoventilation.*

   a. Obstruction of the air passages (larynx, trachea, bronchi), *e.g.*, drowning, asthma.
   b. Pulmonary disturbances that prevent alveolar ventilation: alveolitis, edema, toxic gases, emphysema, pneumonia, atelectasis, etc.
   c. Inadequate expansion of the lung, of pulmonary or extrapulmonary origin: pneumothorax, pleural effusion, emphysema, pulmonary fibrosis, atrophy of the respiratory muscles, etc.
   d. Insufficient pulmonary ventilation, due to depression of the respiratory center.
   e. Shallow breathing due to shock, pneumonia, bronchopneumonia, postoperative pain, neurasthenia, fatigue, etc.

3. *Short circuit between the right and left sides of the heart or in the pulmonary circulation.* In such cases the blood passing through the lung is well oxygenated but is mixed with venous blood that has not passed through the lung:

   a. Congenital heart disease, interauricular or interventricular septal defects, etc.
   b. Arteriovenous aneurysms in the pulmonary circulation.
   c. Passage of blood through parts of the lung that are not ventilated, pneumonia, atelectasis.

4. *Retarded diffusion of gases due to alterations in the alveolar epithelium* and perhaps in the vascular endothelium.

Anemic anoxia. In this type of anoxia the gaseous exchanges in the lung are carried out normally, and the oxygen tension in the blood is normal, but the oxygen capacity of the blood is below normal because there is a decrease in hemoglobin or because the latter is altered or is partially combined with some gas other than oxygen; the total volume of oxygen is therefore diminished. If the condition is not very severe, the amount of oxygen in the blood can be sufficient in resting conditions, but oxygen want is made evident in muscular exercise because the oxygen reserve is below normal. This type of anoxia is due to the following causes:

1. *Hemoglobin insufficiency,* acute and chronic hemorrhage, severe anemia.
2. *Alteration of hemoglobin,* formation of methemoglobin in cases of intoxication by nitrite, chlorate, aniline, etc.
3. *Combination of hemoglobin with gases other than oxygen,* CO intoxication (see page 30).

Stagnant anoxia. This type of anoxia results from slow circulation of the blood in the capillaries due to general or local causes. Blood is normally oxygenated in the lungs, but it circulates slowly through the capillaries and the tissues do not receive adequate amounts of oxygen. Owing to the slow circulation, the CO_2 content of the blood increases abnormally, the release of O_2 from hemoglobin is thus facilitated, and the want of oxygen is partially compensated. Stagnant anoxia can affect the whole organism, or be localized to one vascular territory. It is due to the following causes:

1. *Central circulatory disturbance,* heart insufficiency.
2. *Peripheral circulatory disturbance,* circulatory collapse.
3. *Local anoxia,* local stenosis or arterial spasms, venous obstruction.

Histotoxic anoxia. In this type of anoxia the oxygenation and circulation of the blood are normal but the oxidative mechanisms of the tissues are disturbed. Any drug that depresses cell respiration causes it; the most typical is cyanide, but H_2S, narcotics, and other drugs also produce it. The particular ways in which the different drugs act on the oxidation-reduction mechanism are described in treatises on cell respiration.

Symptoms of anoxia. Anoxia can be either acute or chronic. The signs and symptoms of acute anoxia are similar to those of alcohol intoxication; those of chronic anoxia resemble those of fatigue.

Mammals, including man, do not tolerate acute anoxia; after a few minutes in an atmosphere free from oxygen or with a low oxygen tension, severe symptoms become evident, and death follows. If the subject recovers, permanent injury may remain. Anoxia, therefore, not only stops the organic functions but also damages them. Organs most sensitive to anoxia are the central nervous system and the heart.

Nervous symptoms: headache, depression, apathy, slowness of thought, or else excitement, loss of control, loss of memory and the idea of time,

intellectual errors, emotional reactions, inefficient muscular coordination, asthenia, weakness, fatigue, somnolence or insomnia. In an advanced stage there are disturbances in the senses (vision, hearing, pain, etc.).

Digestive symptoms: nausea, vomiting.

Circulatory symptoms: tachycardia, slight hypertension, cyanosis, disturbances in the electrocardiogram, nasal hemorrhage. In advanced stages: heart failure, dilatation of the heart, bradycardia, sudden fall in blood pressure, syncope.

Respiratory symptoms: increased pulmonary ventilation, tendency to periodic respiration, especially during sleep.

Permanent sequelae of severe anoxia are due to degenerative lesions in the central nervous system, especially in the cortex and the subcortical nuclei.

Special Forms of Anoxia

Anoxia can be established rapidly (acute anoxia) or gradually (chronic anoxia). In chronic anoxia there are compensatory reactions that adapt the organism to the lower oxygen tension. These have been well studied in the acclimatization to high altitudes.

Mountain sickness. This disturbance is due to anoxic anoxia; it is called "*soroche*" in Peru and "*puna*" in the plateaus of the southern Andes.[1] As altitude increases the barometric pressure falls (see Chap. 27); therefore oxygen tension also falls, and the percentage of oxyhemoglobin in blood diminishes. The signs and symptoms of mountain sickness are due to the decrease in oxygen tension. Exercise increases the severity of the condition because it increases the need for oxygen.

A rapid ascent to high altitude in an airplane provokes symptoms similar to those produced by sudden decompression in divers. In both cases gaseous nitrogen is released in the tissues (see "Accidents due to decompression," page 313). In the pathogenesis of these disturbances a rapid fall from 4 atmospheres to 1 atmosphere has the same effect as a drop from 1 to ¼ atmosphere.

Mountain sickness appears at different oxygen tensions according to whether the subject has become acclimatized or not, or is active or resting; there are also considerable individual variations. The first signs appear at heights between 9,000 and 10,000 ft. (3,000 m.). Oxygen tension at 10,000 ft. is 110 mm. Hg and it is 66 mm. Hg at 22,000 ft. Higher altitudes can be reached by unacclimatized persons without danger only if oxygen is breathed; usually aviators begin to breathe oxygen at even lower levels.

In 1875 three French scientists ascended in a balloon to a height of 26,000 ft. (8,600 m.); at about 25,000 ft. (7,500 m.) consciousness was lost and only one of them, Tissandier, survived. After several unsuccessful attempts, in some cases with loss of lives, on May 29, 1953, the peak of Mt. Everest, slightly over 29,000 ft., and the highest on earth, was reached by Hillary and Tenzing, members of the British Mt. Everest Expedition, led by Sir John Hunt. The last thousand feet were the most difficult to climb, and it was necessary to breath pure oxygen (3 to 4 liters per min. in an open circuit) in order to keep going.[1]

The response of the organism to high altitude has been the subject of considerable research in permanent and temporary laboratories established at great heights in different parts of the world. Mosso organized the laboratory on the Gnifetti peak of the Monte Rosa in the Italian Alps at 15,000 ft. The Peak of Tenerife (11,000 ft.), Pike's Peak (14,000 ft.), and the Cerro de Pasco in Peru (14,000 ft.) have been the sites of famous expeditions. Work in the laboratories on the Jungfrau and Davos in Switzerland, and at the camp at Auncanquilcha (20,000 ft.) in Chile has also given many interesting results. The University of San Marcos, Lima, Peru, has an Institute of Andean Biology with a permanent laboratory situated 90 miles from Lima, at Morococha, which is 14,900 feet above sea level. The University of California operates the White Mountain high-altitude research station, with laboratories at 10,600 and 12,500 ft. The effect of low pressure has also been studied in hermetically sealed steel chambers in which a pneumatic pump can produce any required pressure (decompression chambers). These decompression chambers are in use at the principal aviation fields to test the candidates for aviation pilots. They cannot be used for studies of acclimatization, as this requires days or even weeks.

[1] Mountain sickness is observed in subjects living at 10,000 ft. (3,000 m.) or more above sea level. Aviation sickness is due to sudden and repeated exposures to low barometric pressures for a short time.

[1] Hunt, J., "The Ascent of Everest," Hodder and Stoughton, London, 1953.

There is wide variation in the responses of different individuals. They begin at lower levels in some subjects than in others. Physical exercise, such as is performed when climbing a mountain, exposure to cold, wind, etc., increase the need of oxygen and accelerate the appearance of in oxygen tension and not the decrease in barometric pressure.

Other signs and symptoms that appear at about 10,000 ft. are tachycardia, sometimes premature beats, increased respiratory frequency, fatigue, insomnia, etc. After 2 to 4 days'
FIG. 155. Total pressure and partial pressure of gases in the alveolar air at different altitudes. (*Fulton, J. S., et al. "Decompression Sickness," Saunders, Philadelphia, 1951.*)

the response. If pure oxygen is breathed instead of air, the critical point of oxygen insufficiency is shifted upward; instead of 9,000 to 10,000 ft. (3,000 m.), it is 38,000 ft. (12,000 m.). CO_2 partial pressure and tension of water vapor remain constant (Fig. 155).

The disorders arising in the nerve centers are due to cerebral anoxia. There is loss of memory, errors are committed when making simple arithmetical calculations, and there are also errors of judgment. For instance, when Haldane wished to observe his own cyanosis while being submitted to a total pressure of 320 mm. Hg in a decompression chamber, he kept searching for his image on the back of the mirror. Dizziness, headache, and vomiting then occur, and as the barometric pressure falls the subject becomes excited. If the pressure is lowered even more, progressive paralysis makes its appearance and death may occur.

These disorders are not observed if the subject breathes pure oxygen instead of air at these same pressures; they are therefore due to the decrease

exposure to this altitude the symptoms begin to recede gradually.

The decrease in the oxygenation of the blood causes cyanosis, which is easily observable in the lips and nails and rapidly increases with exercise.

One of the first symptoms to appear is an increase in pulmonary ventilation, due at first to increase in depth, and later also in frequency, of breathing. This is observed when the oxygen falls to the equivalent of 13 per cent at sea level, but in some cases it begins at an oxygen partial pressure corresponding to 18 per cent oxygen at sea level. This increase in pulmonary ventilation is caused by an increase in the excitability of the respiratory center due to the stimulation by anoxia of the chemoreceptors in the aortic and carotid bodies. It increases the elimination of CO_2, and CO_2 concentration falls in the alveolar air and in the blood (acapnia). The loss of free CO_2 modifies the ratio of free CO_2 to combined CO_2, therefore the hydrogen ion concentration in the blood diminishes. This disturbance in the acid-base equilibrium is com-

pensated by the elimination of base by the kidneys, until the normal ratio is restored. Acclimatized individuals have a lower alkali reserve than normal at sea level. This does not mean that the acid-base equilibrium is disturbed in high altitudes, but that it is adjusted to the new conditions in which the organism finds itself. This decrease in alkali reserve is not, therefore, a condition of acidosis. A subject acclimatized to an altitude of 15,000 ft. has different physiologic constants from those normal for sea level.

Acclimatization to high altitude, or conversely from high altitude to sea level, takes place gradually. With respect to the acid-base equilibrium and respiratory conditions, the adjustment takes about a month to establish.

Normal CO_2 tension in alveolar air is more or less 40 mm. Hg at sea level; at an altitude of 14,000 ft. it falls gradually and becomes stabilized at 26 mm. Hg after 35 days. The respiratory minute volume at rest remains stable at a figure 50 per cent above that at sea level. In acclimatized subjects there is a close relationship between the level to which they are adapted and the alveolar CO_2 tension.

Considering only these factors, the unacclimatized individual is at a disadvantage for three reasons: (*a*) he has a lower oxygen concentration in arterial blood; (*b*) he has a lower oxygen tension; (*c*) his blood is more alkaline, a condition that is unfavorable for the dissociation of oxygen from oxyhemoglobin.

The decrease in alveolar CO_2 tension permits a corresponding increase in alveolar oxygen tension, which compensates in part the anoxic condition.

Individuals of a community that has lived at high altitudes for several generations show another type of adaptation. Barcroft reports that the Cholos who live on the Peruvian plateau have ribs placed more horizontally, so that the transverse diameters of the thorax are relatively larger and the vertical diameter less than in persons living at sea level; the thorax thus has a larger volume in the inhabitants of the plateau.

Another important change in acclimatization is the increase in erythrocyte (polycythemia) and hemoglobin concentration. Polycythemia is observed immediately on exposure to high altitude; this is due to contraction of the spleen caused by anoxia, a fact that has been demonstrated experimentally. The total amount of red cells in the organism is not increased, but those stored in the spleen are poured out into the circulation, and there is an increase in the circulating blood volume. Polycythemia persists in subjects living at high altitude, and many theories have been put forward to explain this so-called secondary polycythemia, such as a longer life span of the red cells, an increase in blood concentration due to the evaporation of water, etc. The true cause of polycythemia is an increase in the activity of the hemopoietic tissue in the bone marrow. Chronic anoxia of other origins, such as chronic CO intoxication, also provokes polycythemia. This greater activity of the bone marrow is made evident by an increase in reticulocytes. Regeneration of red cells after experimental hemorrhage in dogs also takes place at a faster rate in animals at high altitudes than in those at sea level. After a few weeks, sometimes months, of living at high altitude the erythrocyte count is stabilized at a level above the normal for sea level; there is a certain relationship between the erythrocyte and hemoglobin concentration, on the one hand, and the height above sea level, on the other.

Barcroft found an increase in the oxygen-carrying capacity of hemoglobin in persons living at high altitudes, but this fact has not been confirmed by other workers. Hurtado has observed an increase in myohemoglobin in acclimatized persons.

Monge[1] has described a chronic form of mountain sickness in which the patients cannot adapt themselves or have lost the capacity of adaptation to high altitude. The abnormal condition persists as long as the subjects remain at high altitude, and rapidly disappears on their return to sea level. Irreversible damage (heart disease, etc.) may be suffered if such persons live several years at high altitude without achieving satisfactory acclimatization.

Decrease in oxygen concentration. This condition is found at normal or even high barometric pressure, in a closed environment such as mines, if the air is vitiated by inert gases, such as methane. Signs and symptoms of anoxia appear when the oxygen concentration falls to 13 per cent. In mines, CO is also formed, but this causes anoxia by a different mechanism.

Anoxia due to pulmonary disease. Any disease of the lung that diminishes the surface of gaseous exchange by a certain extent causes

[1] MONGE, D., *Science*, **95**, 79, 1942.

anoxia. Pulmonary diseases are particularly serious where the barometric pressure is low, because two factors that cause anoxia are present at the same time. Pneumonia at an altitude of 15,000 or 20,000 ft. is almost certainly fatal, and if possible the patient should be brought down to sea level, or at least adequately treated with oxygen.

Pulmonary diseases cause anoxia in several ways. In pulmonary edema the alveoli and small bronchi are obstructed by fluid; in bronchopneumonia they are filled with secretions. In asthma air circulates with difficulty because of spastic contraction of the smooth muscles of the small bronchi. In pneumonia the consolidated area does not receive air; during the first stages the blood vessels of the diseased area are still patent but the blood does not come in contact with the air, so it returns to the heart in a venous condition, where it is mixed with blood which has been arterialized in the normal areas. There is also shallow breathing in these patients, and therefore insufficient alveolar ventilation. In certain chronic diseases of the lung, such as emphysema, the alveolar walls suffer structural changes which obstruct gaseous interchange. In other chronic diseases, such as Ayerza's disease, chronic anoxia provokes some of the effects observed in mountain sickness, *e.g.*, polycythemia due to stimulation of the hemopoietic tissue in the bone marrow.

Fetal anoxia. According to Barcroft, who has extensively studied fetal respiration, fetal blood is normally in a state of anoxia, due to the conditions of gaseous interchange in the placenta. The fetus has polycythemia provoked by this anoxia, but after birth rapidly becomes "acclimatized" to the new condition of life.

CYANOSIS

Cyanosis is a dark blue or violet color of the skin and mucosae, observed when the blood in the surface capillaries contains a certain proportion of nonoxygenated hemoglobin, or hemoglobin compounds such as methemoglobin or sulfhemoglobin. Not all compounds of hemoglobin produce cyanosis; thus in CO intoxication the skin is pink, because of the cherry-red color of HbCO.

Cyanosis is observed when 5 gm. per cent or more of the hemoglobin in the capillaries is in the nonoxygenated state. Sometimes cyanosis is provoked by 4 gm. per cent of hemoglobin in this condition and other times 6 gm. per cent is needed.

There are four factors in the production of cyanosis: (*a*) total hemoglobin concentration in blood; (*b*) degree of oxygenation of the blood leaving the lungs; (*c*) the proportion of arterial to venous blood when these are mixed, as in congenital cardiac malformation; (*d*) removal of oxygen from the blood as it passes through the capillaries.

The intensity of cyanosis is modified by certain factors that facilitate or obstruct the observation of the color of the blood in the capillaries: thickness of the skin overlying the capillary network; diameter, length, and number of capillaries in a given area of skin or mucosa; pigmentation of the skin, normal (Negroes, Mongols) or abnormal (deposits of silver or gold, Addison's disease, jaundice); conditions of the blood plasma (pigments, chylomicrons, leukocytosis, etc.). Cyanosis can be more easily detected in areas where the skin is fine, poorly pigmented, and well vascularized, *e.g.*, lips, nose, ears, cheeks, finger tips, and especially over the root of the nails. In the course of surgical operations the color of the blood can be noted in the viscera or directly as it flows from the blood vessels.

The intensity of cyanosis is due essentially to the absolute amount of nonoxygenated hemoglobin; therefore the best way of measuring it is by determining the amount of nonoxygenated hemoglobin in capillary blood. Total hemoglobin is determined, then the percentage of nonoxygenated hemoglobin in arterial and in venous blood; the average of these figures is the one corresponding to capillary blood.

For example, in a subject with normal blood, the total oxygen capacity is 20 cc. per cent. Arterial blood carries 19 cc. per cent O_2; therefore there is the equivalent of 1 cc. per cent nonoxygenated hemoglobin. As 1 gm. hemoglobin carries 1.34 cc. O_2, there is 0.74 gm. hemoglobin. Venous blood carries 14 gm. per cent oxygen; there is therefore the equivalent of 6 cc. per cent (4.47 gm.) nonoxygenated hemoglobin. In the capillaries there is $(1 + 6)/2 =$ 3.5 cc., *i.e.*, 2.6 gm. hemoglobin. This figure is below the threshold of cyanosis.

In a subject with cyanosis the total oxygen capacity is 20 cc. per cent. Arterial blood carries 16 cc. per cent; the equivalent of 4 cc. per cent remains unsaturated. Venous blood carries 10 cc. per cent; the

equivalent of 10 cc. per cent remains unsaturated. In capillary blood there is $(4 + 10)/2 = 7$ cc., which corresponds to 5.22 gm. nonoxygenated hemoglobin.

Cyanosis is closely connected with anoxia, but the two terms do not have the same significance. For example, in severe anemia there is anoxia, but no cyanosis, because there is not enough hemoglobin. In polycythemia there can be cyanosis without anoxia. In anoxia due to CO intoxication and in histotoxic anoxia there is no cyanosis. "Anoxia" and "cyanosis" are not, therefore, equivalent terms.

Classification of cyanosis. *Arterial* or *central cyanosis.* In this type the blood passes through a normally ventilated lung but is not sufficiently oxygenated. The condition can be provoked by

1. Decrease in oxygen tension in inspired air, due to
   - *a.* Breathing air contaminated with inert gases.
   - *b.* Breathing in closed atmospheres where oxygen is consumed and inadequately replaced (mines, submarines).
   - *c.* Low barometric pressure (high altitudes; decompression chambers).
2. Insufficient alveolar ventilation, due to
   - *a.* Shallow breathing (thoracic pain, pneumonia, bronchopneumonia, encephalitis, hysteria, neurasthenia, postoperative conditions, etc.).
   - *b.* Diminished respiratory rate (narcosis, encephalitis, etc.).
   - *c.* Obstruction of the air passages (larynx, trachea, bronchi), asthma, bronchopneumonia, etc.
   - *d.* Diminished pulmonary expansion (narcosis, emphysema, sclerosis, Ayerza's disease, pleural effusion, pneumothorax, etc.).
3. Short circuit between venous and arterial circulation, due to
   - *a.* Short circuit between the right and left sides of the heart (interauricular or interventricular orifices; pulmonary arteriovenous fistula, etc.).
   - *b.* Passage of blood through unventilated areas of the lung that have patent blood vessels (atelectasis, pneumonia, pulmonary congestion, edema, etc.).

In all the cases listed under 1 and 2, the administration of oxygen diminishes cyanosis. In the cases listed under 3, the administration of oxygen does not diminish cyanosis except in cases of pneumonia in which cyanosis is due mainly to shallow breathing (2*a*).

Peripheral cyanosis. In this type the blood loses a large proportion of oxygen to the tissues, owing to slow circulation through the capillaries or to anoxic anoxia. If there is circulatory stasis, there is also venous hypertension. Peripheral cyanosis can be general or local. It is due to

1. Congestive cardiac decompensation. If pulmonary congestion is marked, central cyanosis, due to insufficient oxygenation of the blood, will be added.
2. Venous obstruction (mediastinal tumor, mitral stenosis, stenosis of the pulmonary artery, etc.).
3. Peripheral circulatory insufficiency (circulatory collapse in shock, infections, intoxications, etc.).
4. Arteriolar or venous spasmodic vasoconstriction, with capillary dilatation (Raynaud's disease, cold, acrocyanosis, etc.).
5. Combination of two causes of anoxia, or of anoxia with increased oxygen consumption (physical exercise at high altitudes; cardiac and pulmonary diseases at high altitudes, which are well compensated at sea level).

Cyanosis of exclusively peripheral origin is not improved by oxygen. Local cyanosis due to vascular spasm is improved by submerging the affected limb in water at 45°C., which relieves the spasm.

Cyanosis due to alterations in hemoglobin. This type of cyanosis is due to

1. Formation of methemoglobin (intoxication by sulfanilamide, aniline, nitrobenzene, nitrites, etc.).
2. Formation of sulfhemoglobin (intoxication by H_2S, enterogenous autotoxic cyanosis or Stovkis-Talma syndrome).

THERAPEUTIC USE OF OXYGEN AND CARBON DIOXIDE

Pure oxygen at a pressure of 4 to 5 atmospheres is toxic and rapidly fatal. The majority of animals die after a few days in an atmosphere with 70 to 80 per cent oxygen, but 50 per cent is well tolerated. Breathing more than 60 per cent oxygen at normal pressure is toxic for man after a few hours. The onset and severity of

symptoms depend on the oxygen partial pressure in the air inspired, the duration of exposure, and individual sensitiveness; this last factor has considerable importance in modifying the severity of the symptoms. Pure oxygen should, therefore, not be given for more than a short time. Moreover, it is usually not necessary to do so, because satisfactory results are obtained with 60 per cent oxygen in all but a few exceptional cases.

Breathing pure oxygen at sea-level pressure for several hours produces irritation of the respiratory tract in normal subjects. There is also retrosternal pain, and the vital capacity diminishes. In 82 per cent of the subjects retrosternal pain appears in 4 to 22 hr. of exposure to pure oxygen.[1] This symptom gradually subsides when air is again breathed; usually it disappears in less than 12 hr. Breathing 75 per cent oxygen provokes symptoms in 55 per cent of the subjects, but none is provoked when 50 per cent oxygen is breathed. The reactions are due exclusively to the high oxygen tension. Breathing air at high pressure does not produce them. They are not due to lack of nitrogen, because breathing pure oxygen in a decompression chamber at 380 mm. Hg does not provoke them. At this pressure pure oxygen is at the same partial pressure as 50 per cent oxygen at sea-level pressure.

Breathing pure oxygen at 2 or more atmospheres causes predominantly signs of disturbance of the cerebral cortex, *e.g.*, epileptoid convulsions. In experimental animals, permanent lesions and death have been observed.

The administration of oxygen at concentrations higher than in air increases the oxygen tension in alveolar air and its diffusion into the blood; hence its efficiency in the treatment of certain types of anoxia.

Breathing oxygen is highly beneficial when the oxygen tension is low, as in high altitudes (aviation), when the air is vitiated (mines), when there is mechanical obstruction of the air passages (drowning), in respiratory depression (circulatory collapse, anesthesia), when gaseous exchange in the lung is obstructed (pneumonia), in pulmonary edema (poison gases, heart disease), in carbon monoxide intoxication, whenever artificial respiration must be performed, in emphysema, and in asthma. In all these cases the higher oxygen tension increases oxygen diffusion into the blood and a higher degree of oxygenation of hemoglobin is assured.

Breathing oxygen has no beneficial effects in other forms of anoxia. In anemia, and in cases of intoxication with conversion of hemoglobin into methemoglobin, anoxia is due to the decrease of hemoglobin, but the hemoglobin present is 95 per cent saturated with O_2; oxygen inhaled does not significantly increase this proportion nor the amount of O_2 dissolved in the plasma. Oxygen therapy is not efficacious in stagnant anoxia unless there is extensive congestion or edema of the lungs. In stagnant anoxia, hemoglobin leaves the lungs normally oxygenated, so any increase in the alveolar oxygen tension will have little effect. In histotoxic anoxia (*e.g.*, cyanide intoxication), there is no oxygen want, but there is incapacity to utilize oxygen; therefore in these cases oxygen therapy is not efficacious.

Oxygen therapy should not be applied in chronic anoxia (except in the acute stages) because it interferes with the activity of compensatory mechanisms, and after oxygen administration is discontinued the patient is in worse condition than before the treatment.

In cases in which oxygen therapy is efficacious the patient improves rapidly, dyspnea ceases, and the circulation improves. If there is fever, as in pneumonia, the temperature falls.

Oxygen therapy is not efficacious if the oxygen is not given in the proper conditions.[1] It should be administered continuously over several hours, and sometimes days. The oxygen reserve in the organism is sufficient for only a few minutes; and this reserve is diminished in anoxia. Suppression of oxygen, even for a few minutes, can be more harmful than the complete absence of oxygen therapy, because in the latter condition compensatory mechanisms are active, which oxygen therapy suppresses.

Oxygen should be given in an adequate concentration. The use of a funnel or a tube placed near the nasal orifices is not efficacious. Oxygen masks are useful in certain cases such as asphyxia due to CO poisoning, drowning, anoxia of aviators flying at high altitudes, and when the treatment is necessary for only a few minutes or, at most, a few hours. In the treatment of anoxia due to disease, when oxygen must be administered over long periods, oxygen tents (Fig. 156)

[1] Comroe, *et al.*, Oxygen Toxicity, *J. A. M. A.*, **128**, 710, 1945. (A very good bibliography of the subject is given.)

[1] It is not necessary to administer the 99 to 99.5 per cent "medicinal" oxygen; 98 per cent oxygen prepared for industrial uses is quite as efficient, has no drawbacks, and is considerably less expensive.

or masks that cover all the face must be used, or a catheter should be placed inside the nasal cavity.

Oxygen tents are made of impermeable material with plastic windows. They are hung over the head of the patient's bed and the folds tucked beneath the mattress. The patient consumes only 0.5 liters per min. of oxygen, but because of unavoidable leakage, it should be administered at a rate of 8 liters per min., if the oxygen concentration is to be kept at 60 per cent. CO_2 eliminated by the patient tends to accumulate within the tent, but a CO_2 concentration of 1.5 to 2 per cent is not harmful. It is important to keep the air within the tent dry and cool; otherwise the atmosphere easily becomes intolerably damp and hot. The air in the tent is made to circulate through a cooler containing ice or an electrically operated air-conditioning apparatus, where the temperature is lowered and the water breathed out by the patient is condensed.

FIG. 156. McKesson's oxygen tent. The receptacle beside the bed contains ice to cool and dry the air. Note the tubes for circulation of air between tent and cooler.

Oxygen can be administered efficiently by means of a catheter introduced into the nose, with its tip in the nasopharynx. Oxygen is first made to bubble in water and is then passed through the catheter at a rate of 4 to 6 liters per min. The inspired air contains approximately 60 per cent oxygen, and some patients find this procedure more comfortable than an oxygen tent.

Helium has been used as a therapeutic agent by Barach.[1] This gas is very light and noninflammable. Its atomic and molecular weight is 4, and its density compared with that of hydrogen (H_2) is 2. The density of nitrogen (molecular weight 28) is 14. Artificial air is made up of 21 per cent O_2 and 79 per cent helium. Helium, owing to its lightness, passes through the small bronchi and alveolar ducts much more easily than ordinary air. It has been used with good results in the treatment of asthma.

[1] BARACH, A. L., *J. A. M. A.*, **107**, 1273, 1936.

Carbon dioxide was first used in the treatment of anoxia by Yandell Henderson. A mixture of 95 per cent O_2 and 5 per cent CO_2, sometimes called "carbogen," is frequently used.

In normal subjects concentrations of CO_2 below 2 per cent in air with 20 per cent O_2 do not modify the respiratory rhythm. A small increase in CO_2 concentration increases the depth of breathing, which increases by 30 per cent when 2 per cent CO_2 is breathed. Concentrations of 4.5 to 5 per cent CO_2 cause some difficulty in breathing, sometimes nausea and malaise, and a slight increase in respiratory frequency. A concentration of 8.5 per cent produces dyspnea and arterial hypertension, which become very distressing after 15 to 20 min. but which rapidly disappear on breathing air. The upper limit tolerated lies between 7 and 9 per cent; higher concentrations (10 to 11 per cent) cause incoordination of movements and loss of consciousness. The response is even more marked with concentrations of 15 and 20 per cent, which are nevertheless tolerated up to 1 hr. by experimental animals. Concentrations of 25 to 30 per cent cause circulatory and respiratory depression, progressive loss of reflexes, coma, and death.

The reasons for administering CO_2 in ade-

quate concentrations are the following: Acute anoxia increases the excitability of the respiratory center reflexly by stimulating the chemoreceptors in the carotid and aortic bodies, but sufficiently intense or prolonged anoxia depresses the respiratory center and breathing becomes shallow. This is due to an exaggeration of the Hering-Breuer reflex, and anoxia is thus increased because of insufficient alveolar ventilation. At the same time there are serious disturbances in the tissues, especially in the myocardium and the central nervous system. Base migrates from the blood to the tissues. The importance of this acidosis of asphyxia has not been clearly established. If anoxia has not reached an advanced stage, artificial respiration with air or oxygen is sufficient to restore the patient to a normal condition, but if anoxia has been prolonged to a more serious stage, artificial respiration is no longer efficacious and the patient dies. If 95 per cent O_2 and 5 to 7 per cent CO_2 is used instead of air or oxygen, he is rapidly restored. A completely satisfactory explanation of the mechanism by which CO_2 acts in this case has not been given. Apparently the nerve centers (respiratory and vasomotor), severely depressed by anoxia, are no longer capable of responding to normal CO_2 concentrations; therefore to obtain a response the CO_2 concentration in alveolar air (and in the blood) should be raised. Pulmonary ventilation is then increased, the blood pressure rises, and the heartbeat is stronger.

The most evident effect on respiration of this treatment is the increase in its depth, which assures a more efficient alveolar ventilation and prevents or suppresses atelectasis by the wider expansion of the lung. This last effect is of importance in certain conditions in which atelectasis is a factor in pulmonary infection, as in postanesthetic atelectasis and the normal atelectasis of the newborn child. In normal babies this factor is not very important, but in weak or premature babies respiratory movements are inadequate and frequently do not expand the lungs completely. CO_2 inhalation is also useful in the shallow breathing of pneumonia, but it should not be administered when there is CO_2 retention as in stagnant anoxia.

Resuscitation. In severe anoxia and asphyxia the respiratory movements cease and serious disturbances in the circulation occur (tachycardia, hypotension, circulatory collapse). The response of the respiratory center is abnormal; it is less sensitive to chemical stimuli, and it can be depressed by substances which normally stimulate it. These respiratory and circulatory disturbances cause damage in the tissues most sensitive to anoxia (myocardium and central nervous system).

Resuscitation consists in rapidly taken measures to prevent irreversible damage to the tissues in cases of asphyxia or anoxia. These measures are artificial respiration, oxygen administration (preferably with 5 to 7 per cent CO_2), and treatment of circulatory collapse. If anoxia is not too severe, artificial respiration and oxygen (together with CO_2) will be enough to restore the patient. More advanced cases will need transfusion of blood or plasma, and the injection of vasoconstrictor drugs. The patient should be kept warm by adequate covering and heating.

ACCIDENTS DUE TO DECOMPRESSION

Accidents due to decompression were first observed in divers, in men working in caissons under water, and in sailors rescued from submarines. These accidents produce a syndrome known as "caisson disease." More recently the same effects have been observed in fighter pilots climbing rapidly to great heights.

A descent of 10 m. (32.8 ft.) below the surface in water causes an increase in pressure equal to 1 atmosphere. The air in the diver's helmet or in the caisson is renewed by pumping it in at a pressure varying with the depth and letting it out by a system of valves. The greatest depths so far reached are the equivalent of 10 atmospheres. The diver feels some discomfort on descending, such as pain in the ear owing to the difference in pressure on both sides of the eardrum, which is relieved by swallowing, thus equalizing the pressures; but serious disturbances occur only when he is returning to the surface, *i.e.*, on decompression.

While the diver is working under a high pressure, gases in the air are dissolved in the blood and tissues proportionately to the partial pressure of the gas, according to Henry's law. As he comes up to the surface, the pressure falls and the gases dissolved in the blood under pressure are released and form bubbles, as in an unstoppered soda-water bottle. Oxygen thus set free is rapidly absorbed by the cells, but nitrogen remains and can obstruct the finer vessels and capillaries (air embolism). These embolisms can

produce serious and even fatal damage when the heart or brain vessels are obstructed. The main symptoms are pain in the joints and bones, commonly known as the "bends"; paralysis caused by gaseous embolism in the spinal cord; and asphyxia and a choking sensation due to the accumulation of nitrogen bubbles in the large veins, the right heart cavities, and the pulmonary vessels.

To avoid accidents, decompression should be carried out gradually, *e.g.*, divers should rise to the surface very slowly. The same is true of a crew leaving a submerged submarine; the sailors are provided with masks and oxygen bags that permit them to remain submerged for some time. Nitrogen can then be gradually eliminated as the blood passes through the lung. When the men have been submitted to great pressures, sometimes several hours is needed to perform decompression safely. If signs or symptoms of caisson disease appear after the men have arrived at the surface, they should be immediately subjected to pressure in special tanks (Fig. 157), and then gradually decompressed. Aviators who must ascend rapidly to great heights are previously made to breathe pure oxygen so as to eliminate the nitrogen dissolved in the blood and tissues. The elimination of nitrogen in the gut in postoperative intestinal dilatation, or in the peritoneum or cerebral ventricles after air has been injected with the purpose of taking x-ray pictures of these cavities, can be hastened by breathing 95 per cent oxygen.[1] The partial pressure of nitrogen in the lungs is thus reduced to a negligible figure, and N is rapidly eliminated from the blood; approximately 60 per cent is lost in the first hour.
FIG. 157. Decompression tank. A patient is being introduced into the tank, in which the pressure will be raised and then very slowly lowered. (*Haldane, J. S., and J. G. Priestly, "Respiration," Oxford University Press, New York, 1935, p. 336.*)

CHAPTER 34

Cell Respiration

OXYGEN COMBINES IN the tissues with several substances with the formation of CO_2 and water. Animals obtain from these oxidation processes the greater part of the energy needed for their bodily activities.

The significance of the term "oxidation" has gradually changed. Originally it was used for processes in which there is fixation of oxygen; later, for processes in which electrons are lost. Usually the following processes are considered as oxidations: (*a*) loss of electrons; (*b*) loss of hydrogen atoms; (*c*) addition of oxygen. Inverse processes are considered as reductions. At first sight it would seem that widely different reactions are grouped under the term oxidation; nevertheless these processes have much in common, and it will be seen how reaction (*c*) can provoke processes (*a*) and (*b*).

Loss of electrons. A typical example of this process is the conversion of cuprous to cupric ion, which can be expressed in a simplified way as follows:

$$\text{(I)} \qquad \underset{\text{Cuprous ion}}{Cu^{+}} \rightarrow \underset{\text{Cupric ion}}{Cu^{++}} + \text{electron}$$
A solution of cuprous ions can be obtained by dissolving cuprous chloride in water. The salt dissociates into Cl^- and Cu^+, but as Cl^- is not modified in the process here considered, it has been omitted in Equation I. Cuprous ions lose an electron when a substance is added to the solution which has a greater affinity for electrons than these ions, *i.e.*, an electron acceptor. For example, ferric chloride has this effect. When dissolved this salt dissociates into Cl^- and ferric ions, and the following reaction takes place:

$$\text{(II)} \qquad Cu^{+} + Fe^{+++} \rightarrow Cu^{++} + Fe^{++}$$
One electron passes from Cu^+ to Fe^{+++}, cuprous ions are oxidized to cupric ions, and ferric ions are reduced to ferrous ions.

A change of valence takes place in this process; there is an increase of one positive valence in oxidation and a decrease in reduction. There is also a change of valence when iodide (I^-) or chloride (Cl^-) ions lose electrons and are oxidized to iodine (I_2) or chlorine (Cl_2). In this case there is a decrease of one negative valence.

Loss of hydrogen atoms or dehydrogenation. This type of oxidation is illustrated by the following equation:

$$\text{(III)} \qquad \underset{\text{Ethyl alcohol}}{CH_3{\cdot}CH_2{\cdot}OH} \rightarrow \underset{\text{Acetaldehyde}}{CH_3{\cdot}CHO} + 2H$$
In this case hydrogen atoms are lost, a process that is not the same as the loss of protons that occurs on dissociation of an acid:

$$\text{(IV)} \qquad \underset{\text{Acetic acid}}{CH_3{\cdot}COOH} \rightleftharpoons \underset{\text{Acetate ion}}{CH_3{\cdot}COO^-} + \underset{\text{Proton}}{H^+}$$
The only difference between the processes of dehydrogenation and loss of electrons is that in the former the electron lost is accompanied by a proton. Equation III could be expressed as a loss of electrons in the following way:

$$\text{(V)} \qquad CH_3{\cdot}CH_2{\cdot}OH \rightarrow CH_3{\cdot}CHO + 2H^+ + 2 \text{ electrons}$$
Addition of oxygen. Oxidation of acetaldehyde into acetic acid can be taken as an example:

$$\text{(VI)} \qquad \underset{\text{Acetaldehyde}}{2CH_3{\cdot}CHO} + O_2 \rightarrow \underset{\text{Acetic acid}}{2CH_3{\cdot}COOH}$$
Dehydrogenation of ethyl alcohol (Equation III) could also be expressed as oxidation by oxygen:

$$\text{(VII)} \qquad 2CH_3{\cdot}CH_2{\cdot}OH + O_2 \rightarrow 2CH_3{\cdot}CHO + 2H_2O$$
Oxygen acts here as a hydrogen acceptor (oxidizing agent) and at the same time is reduced (accepts hydrogen) and forms water. Ethyl alcohol is dehydrogenated (oxidized) and gives acetaldehyde.

Oxidation of acetaldehyde by oxygen (Equation VI) can also be expressed as a dehydrogenation by postulating the formation first of aldehyde hydrate:

$$\text{(VIII)} \quad CH_3{\cdot}CHO + H_2O \rightarrow CH_3{\cdot}CH(OH)_2 \rightarrow CH_3{\cdot}COOH + 2H$$
Finally, the essential unity of all oxidation processes is made evident on considering autooxidation of cuprous ions. Aqueous solutions of cuprous ions absorb oxygen spontaneously according to the following equation:

$$\text{(IX)} \quad 4Cu^{+} + O_2 + 4H^{+} \rightarrow 4Cu^{++} + 2H_2O$$
The protons taking part in the reaction arise from the dissociation of water: $H_2O \rightleftharpoons H^{+} + OH^{-}$. The oxidizing agent is oxygen, which is reduced when water is formed. It could also be said that oxygen acts as a hydrogen acceptor, or that in the presence of protons it accepts electrons.

Since loss of electrons or hydrogen atoms and addition of oxygen are only different aspects of oxidation processes, these terms will be used indiscriminately in the following discussion.

THE MECHANISM OF CELL RESPIRATION

Oxygen is the final oxidizing agent in animal tissues, but there are many intermediary reactions in which other substances act as oxidizing agents, *i.e.*, as hydrogen or electron acceptors. Oxidation-reduction between two substances A and B can be generally expressed as follows:

$$\text{(X)} \quad AH_2 + B \rightarrow A + BH_2$$
B can be oxygen or any other oxidizing substance. A is oxidized and B is reduced.

Substances on which enzymes act are known as substrates. Between a substrate that is oxidized and oxygen, there are intermediary substances that are oxidized and reduced reversibly in the course of the process. If the substrate is represented by AH_2 the first reaction is

$$AH_2 + B \rightarrow A + BH_2$$

then

$$BH_2 + C \rightarrow B + CH_2$$
and so on, until finally

$$2ZH_2 + O_2 \rightarrow 2Z + 2H_2O$$

Substances B, C, D, . . . , Z act together with specific proteins. In some cases these substances are firmly bound to the respective proteins, and they are not easily dissociated. The substance is then called the prosthetic group of the enzyme. If, on the contrary, the complex is easily dissociated, the substance is called a coenzyme. There is no fundamental difference between prosthetic groups and coenzymes, only differences in degree; therefore it might be better to consider these terms synonymous.

Enzymes are proteins, *i.e.*, they are formed by the union of amino acids. The prosthetic groups or coenzymes are of a different structure, and they can be used to classify oxidation-reduction enzymes. The principal enzymes that take part in cell respiration are (*a*) those which have pyridine-nucleotides as coenzymes; (*b*) flavoproteins; (*c*) cytochromes, which have a prosthetic group similar to heme in hemoglobin; (*d*) other enzymes that will be considered later.

Dehydrogenases. Pyridine-nucleotides. Enzymes that act directly in the oxidation of the substrate are usually called "dehydrogenases." Typical examples of these enzymes are those in which activity is dependent on the presence of pyridine-nucleotides.

The term "pyridine-nucleotide" is due to the fact these substances contain nicotinic amide, which has a pyridine ring. Nicotinic amide united to ribose and phosphoric acid forms a nucleotide.

Two pyridine-nucleotides are known. One of them, diphosphopyridine-nucleotide (DPN), also called "coenzyme I" or "cozymase," is formed by the union of the following molecules: 1 nicotinic amide, 1 adenine, 2 ribose, and 2 phosphoric acid; it is therefore a dinucleotide.

The other known pyridine-nucleotide is triphosphopyridine-nucleotide (TPN) which has three phosphate groups instead of two.

```

        ||     ||
ribose —P——————P— ribose-adenine.
        |      |
        OH     OH
```
In TPN there is an additional phosphate group.

Dehydrogenases catalyze the reaction between the substrate and DPN or TPN. The substrate is oxidized, and the nicotinic amide part of the nucleotide is reduced. This is a reversible reaction, and for a substrate AH_2, it can be diagrammatically expressed as follows:
$$AH_2 + (DPN) \rightleftharpoons (DPN)H_2 + A$$

These coenzymes have been found in all living organisms, and they take part in reactions of fundamental importance. On considering carbohydrate metabolism (Chap. 41) it will be seen how in the disintegration of glycogen, or glucose, to lactic acid, there are a series of reactions in two of which DPN takes part. These reactions are the following:

$$\text{Phosphoglyceraldehyde} + PO_4H_3 + DPN \rightleftharpoons$$
$$\rightleftharpoons \text{Diphosphoglyceric acid} + (DPN)H_2$$
$$\text{Pyruvic acid} + (DPN)H_2 \rightleftharpoons \text{Lactic acid} + DPN$$
In the anaerobic process DPN acts as an intermediary between the two reactions; it is reduced in the former and oxidized in the latter. In the presence of oxygen this does not take place because there are mechanisms that permit the oxidation of reduced DPN. In this case, oxygen instead of pyruvic acid is the final oxidizing agent.

Pyridine-nucleotides are not oxidized directly by oxygen, but by other enzymes and their prosthetic groups.

In addition to the phosphoglyceraldehyde and lactic dehydrogenases mentioned above, there are others that also act with DPN. These are malic, β-hydroxybutyric, and alcohol dehydrogenases. Others act in conjunction with TPN, such as glucose-6-phosphate, phosphohexonic, isocitric dehydrogenases, etc.

Flavoproteins. Pyridine-nucleotides can be reoxidized by reacting with flavoproteins, the prosthetic group of which, *i.e.*, flavine-dinucleotide, is a derivative of riboflavin (vitamin B_2).

          (a)                                 (b)
```

Flavine-nucleotide: *a*, oxidized; *b*, reduced. R is ribityl-(phosphate)$_2$ ribose-adenine in the flavine-dinucleotide, and ribityl-phosphate in the flavine-mononucleotide.
As in other processes, the pyridine-nucleotide is oxidized and the flavine is reduced.

$$(DPN)H_2 + \text{flavine} \rightarrow DPN + \text{flavine } H_2$$
Another enzyme of the flavoprotein type oxidizes D-amino acids:

$$R{\cdot}CHNH_2{\cdot}COOH + \text{flavine} + H_2O$$
$$\rightarrow R{\cdot}CO{\cdot}COOH + \text{flavine } H_2 + NH_3$$
$$\text{flavine } H_2 + O_2 \rightarrow \text{flavine} + H_2O_2$$
In this case the flavoprotein is reoxidized directly by oxygen. Enzymes of this type, acting as the only link between the substrate and oxygen, are called oxidases. The above equation represents the activity of D-amino acid oxidase.

Other flavoproteins are not reoxidized directly by oxygen. *In vitro* they can be oxidized by several reagents, *e.g.*, methylene blue. *In vivo* they are reoxidized by other enzymes, the cytochromes.

Cytochromes. The prosthetic group of cytochromes is an iron-porphyrin similar to heme in hemoglobin. Several cytochromes (a_1, a_3, b, c) have been described. The best known is cytochrome c, which has been obtained pure. Other cytochromes have been identified by their absorption spectra, *i.e.*, the property of absorbing light of a given wavelength. Each one of the cytochromes has a typical absorption spectrum that varies according to whether it is in the oxidized or reduced state.

The catalytic effect of the cytochromes on cell oxidations is due to the capacity of their prosthetic group to be oxidized or reduced. They can thus form links in the chain of catalyzers that act in the oxidation of substrates by molecular oxygen.

```

```
Diphosphothiamine.

Oxidized cytochromes have ferric ion (Fe^{+++}) in the porphyrine, which is reduced to ferrous ion (Fe^{++}) in reduced cytochrome. The difference is similar to that between hemoglobin, which has its iron as Fe^{++}, and methemoglobin, which has its iron as Fe^{+++}. It should be noted that hemoglobin combined with oxygen is not generally considered as oxidized hemoglobin. The combination is, in this case, easily reversible; therefore the term "oxygenated hemoglobin" or "oxyhemoglobin" is used to differentiate HbO_2 from truly oxidized hemoglobin, which is methemoglobin.

The mechanism by which cytochromes react with oxygen is not known in detail; cytochrome c is not autooxidizable, *i.e.*, a solution of reduced cytochrome is not oxidized by molecular oxygen.

Cytochrome oxidation is carried out by cytochrome oxidase, Warburg's *Atmungsferment* (German *Atmung*, respiration) or respiratory enzyme. This enzyme is not yet well known; perhaps it is an autooxidizable cytochrome that can oxidize other cytochromes.

A typical reaction of cytochrome oxidase is its combination with cyanide. A very small concentration of cyanide inhibits cytochrome oxidase and almost completely suppresses oxygen consumption in the tissues.

The present knowledge of tissue oxidations is far from being complete, but apparently some substrates are oxidized by a chain of enzymes and coenzymes or prosthetic groups, more or less as follows:

Substrate → dehydrogenase + DPN or
TPN → flavoprotein → cytochrome → O_2

Coenzymes and prosthetic groups. It is useful to recapitulate here some of the facts already mentioned, adding others which have not yet been considered.

Many enzymes are made up of two parts: (*a*) a protein, in the strict sense of the term, *i.e.*, formed only of amino acids; (*b*) a nonprotein moiety. If the nonprotein portion is easily separated from the protein it is called the coenzyme. If, on the contrary, both parts are firmly united the nonprotein part is known as the prosthetic group.

Pyridine-nucleotides take part in the activity of some dehydrogenases; they are nicotinic amide derivatives. Flavoproteins have a derivative of riboflavin as prosthetic group. To this group belong D-amino acid oxidase, xanthinoxidase, and the flavoproteins that mediate in the oxido-reduction between pyridine-nucleotides and cytochromes.

The prosthetic group of cytochromes is an iron-porphyrin similar to heme in hemoglobin.

Catalase also has an iron-porphyrin as a prosthetic group. This enzyme catalyzes the decomposition of hydrogen peroxide and liberates molecular oxygen:

$$2H_2O_2 \rightarrow O_2 + 2H_2O$$

Thiamine combined to two molecules of phosphoric acid forms diphosphothiamine, the coenzyme involved in the transformation of pyruvic acid.

In brewer's yeast diphosphothiamine is the coenzyme of carboxylase, which catalyzes decarboxylation of pyruvic acid as follows:

$$CH_3{\cdot}CO{\cdot}COOH \rightarrow CH_3CHO + CO_2$$
Owing to this activity diphosphothiamine is also known as cocarboxylase.

In animal tissues the reaction is different; decarboxylation and oxidation of pyruvic acid take place, and the products of these processes are further oxidized by way of the tricarboxylic cycle. In B_1 vitamin deficiency, there is an insufficient amount of diphosphothiamine; oxidation

of pyruvic acid is therefore delayed, and it is accumulated in abnormal amounts.

A pyridoxine derivative (pyridoxal phosphate) is the coenzyme of certain amino-acid decarboxylases in bacteria and in animal tissues of DOPA decarboxylase (DOPA = dioxyphenylalanine).

thioethanolamine forms coenzyme A, which takes part in certain acetylation processes. This enzyme is active in the acetylation of choline with formation of acetylcholine, which is of great physiologic importance. Moreover it also seems to play a part in the formation of citric acid (see diagram of tricarboxylic cycle).

Tricarboxylic cycle
All reactions are reversible, but the arrows have been depicted only in one direction, in order to simplify the diagram.

1) $CH_2-CO.COOH$
2) $COOH-CH_2-COH(COOH)-CH_2-COOH$
3) $COOH-CH_2-C(COOH)=CH-COOH$
4) $COOH-CH_2-CH(COOH)-CHOH-COOH$
5) $COOH-CH_2-CH(COOH)-CO-COOH$
6) $COOH-CH_2-CH_2-CO-COOH$
7) $COOH-CH_2-CH_2-COOH$
8) $COOH-CH=CH-COOH$
9) $COOH-CHOH-CH_2-COOH$
10) $COOH-CO-CH_2-COOH$
11) $CH_3-CO-CH_2-COOH$

Pyridoxal phosphate is also the coenzyme of transaminases. Aspartic-transaminase catalyzes the following reaction:

$$\underset{\text{Aspartic acid}}{COOH{\cdot}CH_2CHNH_2{\cdot}COOH} + \underset{\alpha\text{-Ketoglutaric acid}}{COOH{\cdot}CH_2{\cdot}CH_2CO{\cdot}COOH} \rightleftharpoons \underset{\text{Oxalacetic acid}}{COOH{\cdot}CH_2{\cdot}CO{\cdot}COOH} + \underset{\text{Glutamic acid}}{COOH{\cdot}CH_2{\cdot}CH_2CHNH_2{\cdot}COOH}$$
Alanine-transaminase catalyzes the following reaction:

$$\underset{\text{Alanine}}{CH_3CHNH_2COOH} + \underset{\alpha\text{-Ketoglutaric acid}}{COOH{\cdot}CH_2CH_2{\cdot}CO{\cdot}COOH} \rightleftharpoons \underset{\text{Pyruvic acid}}{CH_3{\cdot}CO{\cdot}COOH} + \underset{\text{Glutamic acid}}{COOH{\cdot}CH_2CH_2CHNH_2COOH}$$
There are similar enzymes for many other amino acids. Pantothenic acid (see Chap. 49, Vitamins) combined with adenosine, phosphates, and

These facts are summarized in Table 30.

The prosthetic groups of several enzymes are still unknown, *e.g.*, that of succinodehydrogenase, which catalyzes the oxidation of succinic acid to fumaric acid, one of the reactions in the tricarboxylic cycle. The prosthetic groups of monoamino oxidase and histaminase are also unknown.

Although many coenzymes derive from vitamins, others do not, *e.g.*, glucose-1,6-diphosphate which acts as the coenzyme in the conversion of glucose-1-phosphate to glucose-6-phosphate.

The tricarboxylic cycle. Pyruvic acid formed in the disintegration of carbohydrate and the two-carbon-atom units resulting from β-oxidation of fatty acids are metabolized in a complex cyclic process, known as the tricarboxylic cycle. The name comes from the fact that some of the intermediate products, such as isocitric and aconitic acids, have three carboxyl groups.

Oxidation of pyruvic acid results in the formation of acetyl-coenzyme A. In this process a

thermostable factor, diphosphothiamine, takes part.

The cycle begins by the condensation of acetyl-coenzyme A and oxalacetic acid with the formation of citric acid (see diagram). A series of reactions leads to the formation of isocitric acid, then α-ketoglutaric acid, succinic acid, etc., and finally oxalacetic acid is again formed. In each turn of the cycle, two molecules of CO_2 are set free.

Table 30. Vitamins in Enzyme Systems

Vitamin	*Coenzyme or prosthetic group*	*Enzyme*
Nicotinic amide (PP).	Diphosphopyridine-nucleotide and triphosphopyridine-nucleotide	Several dehydrogenases
Riboflavin (B_2)......	Flavine-nucleotides	Flavoproteins, *d*-amino-acid oxidases, xanthine oxidase, etc.
Thiamine (B_1).......	Diphosphothiamine	Enzymes acting on pyruvic acid
Pyridoxine (B_6)......	Pyridoxal phosphate	Transaminases, amino-acid decarboxylases, etc.
Pantothenic acid.....	Coenzyme A	Acetylation enzymes
———	Iron-porphyrins	Cytochromes

The following reactions in the cycle are oxidations: (*a*) the conversion of isocitric acid into oxalsuccinic acid, in which TPN takes part; (*b*) the conversion of malic acid into oxalacetic acid, in which DPN takes part; (*c*) the oxidation of α-ketoglutaric acid and of succinic acid, in which the coenzymes or prosthetic groups are still unknown.

Some of the details in the tricarboxylic cycle still need to be confirmed, but the general outline of the cycle has been solidly established on experimental data. This cycle also explains the interrelation between carbohydrate and fat metabolism, since both have a common path of oxidation. Moreover, some of the amino acids can give rise to certain substances in the cycle. For example, aspartic and glutamic acids can be converted by transamination into oxalacetic and α-ketoglutaric acids. The tricarboxylic cycle, therefore, is a common path in the metabolism of carbohydrates, fats, and proteins.

METHODS OF STUDY

Chemical reactions that take place in the whole animal can be studied by the analysis of substances entering the organism (food, inspired air) and the end products of metabolism in the expired air, urine, and feces. Chemical reactions can be observed in isolated organs perfused with an adequate nutrient fluid, or in slices of surviving tissue, submerged in blood serum or in Ringer's solution. These slices must be extremely thin, so that oxygen and the substances in the nutrient fluid can penetrate rapidly into the tissue; if the slices are too thick the deeper parts are deprived of oxygen and food. The consumption of substances added to the fluid can thus be quantitatively studied by chemical methods; also the oxygen consumption and CO_2 production can be accurately determined. Several microrespirometers have been designed for this purpose. Warburg's is the one most frequently used.

Warburg's apparatus. (Fig. 158.) This consists of a capillary manometer for measuring the changes in pressure occurring in the flask with which it is connected. This flask is submerged in a bath maintained at constant temperature; within it the substance to be studied is placed (tissue slice, minced tissue, enzyme in solution). If only the oxygen consumption is to be determined, a few drops of NaOH are placed in a small central compartment; CO_2 formed is immediately absorbed by the NaOH, so that the changes in pressure are due solely to changes in the amount of oxygen within the flask. It is then easy to calculate, from the fall in pressure registered by the manometer, the amount (in cubic millimeters) of oxygen consumed.

Thunberg's method. Thunberg's tube is a test tube stoppered in such a way that gases can be evacuated and an airtight closure can be made subsequently. In this tube the speed of reduction of methylene blue or similar dyes can be measured. If a solution of an enzyme together with a substrate and methylene blue is placed in a Thunberg tube and the substrate is oxidized, methylene blue will be reduced. On reduction, the dye is converted into its colorless leukobase; therefore the velocity of decoloration

of the dye is a measure of the velocity of oxidation of the substrate. Moreover this velocity is proportional to the enzyme concentration. A vacuum must first be made within the tube, because the leukobase is autooxidizable, so that if oxygen were present the dye would be reoxidized continuously and would never lose its color.

Inhibitors. Many of the intermediary reactions take place one after the other at approximately equal velocities; therefore the intermediary substrates do not accumulate in appreciable amounts and cannot be measured or isolated. To overcome this difficulty inhibitors that act specifically on one of the reactions only are added to the system; *e.g.*, if fluoride is added, enolase is inhibited and phosphoglyceric acid accumulates. Other examples of more or less specific inhibitors are cyanide, which acts on cytochrome oxidase; monoiodacetic acid, which inhibits phosphoglyceraldehyde dehydrogenase; etc.

Isolation of enzymes. The extraction of minced tissues with water or saline solution yields mixtures of enzymes contained in the tissues. Each one of the enzymes must then be separated from the others. This can be accomplished in some cases by fractional precipitation with salts, or by organic solvents, or by adsorption. In other cases a more resistant enzyme is separated from others less resistant by heat, acidification, or treatment with alcohol or acetone.

The study of intermediary carbohydrate metabolism is a good example of the value of this method. At first tissue extracts that converted glycogen into lactic acid were obtained. Then the enzymes were separated one by one, and the products of each reaction were isolated.

Spectrophotometric methods. By measuring the absorption of visible or ultraviolet light it is possible not only to identify some of the components in the oxidation-reduction enzyme system, but also to measure the velocity of the reactions.

Reduced pyridine-nucleotides show an absorption band at a wavelength of 345 mμ, (1 mμ = 10 A). The oxidized form does not show this absorption band, therefore it is possible to measure the speed of reduction by the rate of absorption at 345 μm.

Flavines have a yellow color; their reduction can be followed by the naked eye because they lose color. Each one of the cytochromes has typical absorption bands, which change on reduction. For example, with suspensions of brewer's yeast it is easy to observe the absorption band corresponding to reduced cytochrome c at 550 mμ. This band is visible in yeast under anaerobic conditions; but if the suspension is merely shaken in air the absorption band disappears owing to the reoxidation of cytochrome.
FIG. 158. Diagram of Warburg's apparatus. The manometer is a U-shaped tube, filled with a fluid of known density. By means of the screw *S* the fluid is kept at a certain level in the branch of the manometer that does not communicate with the flask, *F*; thus the level of the fluid in the other branch of the manometer measures the pressure in the flask. The reactions take place within *F*, which is submerged in a constant-temperature bath. Solutions can be placed in the lateral compartment *L* and added to the substrate without opening the system. The central tube in *F* is filled with alkali to absorb CO_2 when oxygen consumption is being measured.

SECTION FOUR

Digestion

CHAPTER 35

The General Physiology of Digestion

MAN, LIKE OTHER animals, cannot live without food. Substances that provide the specific mass and energy of living beings, and also those needed to maintain normal metabolism, are called foods. Foodstuffs can be classified (*a*) by their origin, as animal (meat, milk, eggs, fat), vegetable (leguminous plants, cereals, sugars, oil), and mineral (salts, water, oxygen); (*b*) by their chemical nature, as proteins, fats, carbohydrates, salts, water, etc.; (*c*) by their principal function, as energy suppliers (carbohydrates, fats, proteins, alcohol), tissue builders (protein, fats, carbohydrates, and some of the salts), and regulators of metabolism (vitamins, salts, water).

Foodstuffs must be altered before they can be used by the organism. In higher animals this alteration takes place in the digestive tract. In the process of digestion, complex, insoluble substances are changed into simpler, soluble, and diffusible forms that can be absorbed and assimilated. This process is performed by the action of the digestive juices secreted by the glands that pour their secretions into the digestive tract. These juices contain enzymes, which reduce the varied foodstuffs into a few simple substances that can be absorbed. Carbohydrates are transformed principally into glucose, fructose, and galactose; fats into fatty acids and glycerol; and proteins into simple amino acids. Water and salts pass through the digestive tract and are absorbed without any appreciable change.

Foodstuffs progress along the digestive tract and are mixed with the digestive juices by the movements of the different segments.

The digestive tract is formed by two or three muscular layers, lined internally by a mucosa, and covered, in parts, by a serous membrane. The mucosa has its origin in the endoderm. In the mouth the mucosa is a squamous stratified epithelium. The lower pharynx and the esophagus are lined by stratified pavemented epithelium. On the gastric side of the cardia there is an abrupt change to simple cylindrical epithelium, which lines the stomach and small and large intestines down to about 2 cm. from the anus, where the epithelium again becomes stratified and pavemented.

The cells of the mucosa lie on the lamina propria of the chorion. In most parts of the digestive tract there is a muscularis mucosae below the chorion, separated from the muscular layers by relatively lax connective tissue (submucosa). The mucosa of the small intestine is folded into villi, and the surface of absorption is thus increased considerably.

The digestive glands. The structure of all the digestive glands follows a similar pattern. The cells of the secretory epithelium form tubes or vesicles of different length and complexity, which communicate, by means of ducts of variable length, with the lumen of the segment of the tract from which they arise. Some of the digestive glands, *e.g.*, the liver, pancreas, and some of the salivary glands, have a single type of secretory cell, but most of them have several types. The glands of the intestinal crypts have at least four kinds of specialized cells; those of the stomach, three; and some of the salivary glands, two. The different types of cells are frequently disposed in separate layers; those that produce a fluid secretion occupy a peripheral situation, and the internal cells secrete a viscous juice rich in organic substances (proteins, enzymes). The more fluid secretion of the external cells can thus flush into the lumen of the gland the secretion of the central cells.

The digestive glands secrete about 5 liters of different juices in 24 hr.; most of this is reabsorbed by the intestine. The greater part of the substances forming this large mass comes from the blood.
Fig. 159. Diagram of five stages in the process of secretion in a cell of the cat's submaxillary gland. *a*, resting cell; the dots represent the granules, the empty space represents the location of the nucleus. *b*, beginning of stimulation of the chorda tympani; the small granules join to form large ones. *c*, stimulation continues; the large granules collect at the distal end of the cell. *d*, stimulation continues; the granules are discharged together with the distal end of the cell. *e*, end of stimulation; the distal end of the cell is restored, and few granules remain. (*Holzlöhner, E., and C. Niessing, Ztschr. f. Biol., vol. 97, p. 563, 1936.*)

The cells of the liver are in direct contact with the blood vessels. The cells of other glands obtain water and crystalloids from the interstitial fluid surrounding the alveoli and tubes. The process of secretion is conditioned, therefore, by the permeability of the capillaries and the permeability of the glandular cells. The latter may vary in different physiologic circumstances, and it probably is not the same in the different types of cell.

Secretion is not a simple process of filtration through the capillaries and glandular cells. The following facts are proof of this assertion:

1. The osmotic pressure of the saliva is more or less one-half that of the blood, varying according to the stimulus which has provoked secretion. If the membranes that separate the blood from the glandular duct were semipermeable, to obtain an ultrafiltrate of this osmotic pressure, hydrostatic pressures of ten to twenty times the blood-pressure level would be needed.
2. Some electrolytes are in higher concentration in the secreted fluid than in blood plasma.
3. If the carotid blood pressure and the pressure in the duct of the submaxillary gland are measured simultaneously, it will be seen that on stimulation of the chorda tympani the pressure in the duct rises and can exceed the carotid blood pressure (Ludwig, 1851).
4. Stimulation of the chorda tympani after atropine has been injected does not provoke salivary secretion, although there is intense vasodilatation.
5. Oxygen consumption increases when the glands are secreting. In the so-called "resting period" the cells continue to consume oxygen and synthesize the specific products of their secretion (protein, enzymes, etc.) which are discharged during the secretory period.

Secretion is, therefore, a special type of cellular activity in which there are two main processes:

1. Transference of water and crystalloids from the blood through the walls of the capillaries and glandular epithelium to the lumen of the digestive tract. In some cases products of glandular synthesis, either inorganic (*e.g.*, HCl in the gastric mucosa) or organic (*e.g.*, bile salts in the liver), are also transferred.
2. Release of organic colloids synthesized by the glandular cells (proteins, enzymes, etc.) which are diluted and flushed out by the fluid passing through the cells.

In most of the secretory cells two parts can be distinguished in the cytoplasm: (*a*) a homogenous optically structureless substance surrounding the nucleus, and (*b*) structural elements such as the mitochondria and Golgi apparatus, which form part of the cell, and the granules which are products of cellular synthesis stored until they are discharged in the process of secretion (Fig. 159). During the resting period these granules accumulate around the nucleus. The Golgi apparatus and the mitochondria are thought to have an active part in their formation.

The granules are the specific products of the glandular cells. They are constituted by proteins, some of which are inert proteins and others enzymes, but mostly enzyme precursors (zymo-

gens) which require an activator to become active enzymes.

Innervation. Ludwig[1] observed that stimulation of the chorda tympani, which innervates the submaxillary gland, provokes salivary secretion, thus discovering secretory nerves. Afterward the dual innervation, sympathetic and parasympathetic, of all the digestive glands was demonstrated.

According to Heidenhain[2] the salivary glands are innervated by two kinds of fibers: (*a*) *secretory fibers* which modify cellular permeability and cause water and salts to be transferred from the interstitial periglandular space to the lumen of the digestive tract; and (*b*) *trophic fibers* which modify the metabolism of the cells, causing them to discharge their specific products into the glandular duct. Babkin[3] considers that Heidenhain's terminology may be confusing and suggests it should be replaced by the terms *hydrelatic effects* (ἐλαύνο, to propel) and *ecbolic effects* (ἐκβαλικός, throwing out). The substitution of "effects" for "fibers" has the advantage of including the activity of hormones, chemical mediators, etc. Moreover, the new terms not only are more expressive than those used by Heidenhain but also have a more precise meaning.

The *hydrelatic function* of the digestive glands is regulated by nerves and hormones. It is under nervous control in the large salivary glands and in the gastric glands during the first phase of secretion, and under hormonal control in the pancreas, liver, intestinal glands, and in the gastric glands during the chemical phase of secretion.

The *ecbolic function* is under nervous control in the majority of the glands. At one time the sympathetic was attributed an almost exclusively ecbolic effect, and the parasympathetic hydrelatic effects. Babkin has demonstrated that in nearly all the digestive glands (salivary, gastric, pancreatic, and intestinal) ecbolic effects are controlled by the parasympathetic. Stimulation of the parasympathetic causes the conversion of organic colloids stored in the cells into soluble products which are discharged into the duct. The sympathetic exerts several kinds of effects: (*a*) it has hydrelatic and ecbolic effects on some of the cells of composite glands, *e.g.*, the semilunar cells of the submaxillary glands and the mucous cells of the gastric mucosa; (*b*) in addition to its vasomotor effects, it innervates contractile myoepithelial cells; (*c*) it has cholinergic fibers which release acetylcholine and produce the same effects as the parasympathetic.

Motility. The muscles of the digestive tract (both striated and smooth) are disposed in various ways in the different segments. They exert several effects: (*a*) they break up and crush the food; (*b*) they mix food with the digestive secretions; and (*c*) they propel the contents of the digestive tract from the mouth toward the large intestine and finally expel the residue. Striated muscles carry out the function of mastication; they are found in the pharynx and upper part of the esophagus, where they take part in the act of swallowing; finally, the external sphincter of the anus is also a striated muscle. All the other segments are provided with smooth muscles, usually disposed in an external longitudinal layer and an internal circular layer; an oblique layer is occasionally found. The coordinated contractions of these muscles and the movements they produce will be described later.

The different segments are separated by *sphincters*, *i.e.*, thickening of the muscle layers and the mucosa; these are the cardia, pylorus, ileocolic sphincter, and internal and external sphincters of the anus.

Properties of digestive smooth muscle. The smooth muscles of the digestive tract form part of Bozler's visceral smooth muscles, which he considers similar to cardiac muscle, syncytial in structure, and with a well-developed automatism.

When a visceral smooth muscle is stretched, it lengthens rapidly and then more slowly, taking a long time to reach its final length. The tension at first rises but then rapidly falls to a low level. Gradual stretching produces little or no rise in tension. A cavity with smooth-muscle walls, *e.g.*, the stomach, can thus be greatly distended without any significant rise in tension. Sudden stretching can produce a much greater and more lasting increase in tension because it stimulates contraction. There is no constant ratio of tension to length, so a muscle can have the same tension at widely different lengths. The "postural tonus" of a viscus, *e.g.*, the "tonus" of the stomach which determines its shape, is dependent on the length of the fibers, not on the tension developed.

Visceral smooth muscles respond to nerve impulses, direct electric stimulation, sudden

stretching, and chemical substances. Among the latter, chemical mediators of neuromuscular transmission (acetylcholine, adrenaline, noradrenaline) are of special importance. The response, which may be contraction or relaxation according to the stimulus and the condition of the muscle, develops slowly. The latent period lasts more than 100 msec., and contraction lasts several seconds; relaxation is even slower. Usually only a small tension is developed on contraction, even when the muscle shortens considerably. Exceptionally strong and sustained contractions are painful (spasms, colic). The response may be localized, or may spread throughout the muscle, accompanied by a spike potential and followed by a refractory period.

Spontaneous rhythmic contractions are frequently observed in visceral muscles. Their amplitude and frequency varies and may be modified (inhibited or augmented) by nerve impulses and their chemical mediators. They have been observed, however, after all nervous influences have been abolished.

Innervation of digestive muscles. The smooth muscles of the digestive tract are innervated by the sympathetic and parasympathetic (extrinsic innervation). Moreover, there are ganglion cells and nerve fibers in the walls of the digestive tract (intrinsic innervation). There are two nerve plexuses in the intestine: (*a*) Meissner's plexus, situated in the submucosa between the muscularis mucosae and the circular muscle layer; and (*b*) the myenteric or Auerbach's plexus, placed between the circular and longitudinal muscle layers.

These plexuses are formed by (*a*) neurons (ganglion cells), usually considered as part of the parasympathetic; (*b*) preganglionic and postganglionic parasympathetic fibers; (*c*) postganglionic sympathetic fibers from the lateral and prevertebral sympathetic ganglia; and (*d*) afferent fibers.

Strips of muscle fibers from the longitudinal layer, free from nerve cells and nerve fibers, show spontaneous rhythmic contraction. In this case rhythmic activity is undoubtedly myogenic. In the intact organism in normal conditions, however, nerve impulses give rise to, and modify, rhythmic contractions.

Propagated contractions in the organism (peristalsis) require the integrity of the nerve plexuses. Cannon's myoenteric reflex, *i.e.*, contraction of the circular layer above, and relaxation below, a stimulated point, in which the plexus plays a necessary part, may, however, not be a true reflex with an afferent and a motor neuron within the plexus, but an axon reflex in which excitation spreads along nerve fibers.

The extrinsic innervation consists of

1. Preganglionic parasympathetic fibers ending on the neurons of Auerbach's plexus. Stimulation of these fibers increases muscular activity in the digestive tract.
2. Postganglionic sympathetic fibers which end on the muscle fibers. Stimulation may produce contraction or inhibition.

The sympathetic exerts a continuous moderating effect, and its removal is followed by augmented motility for a few days; later the denervated segment behaves normally.

Afferent fibers are small nonmyelinated fibers which enter the spinal cord in the dorsal roots. Ascending paths carry impulses from these fibers up to the cortex, and functional integration occurs at the different levels from the cord to the cortex (see Chaps. 73 and 84). Cortical integration of digestive functions explains how these functions are subject to psychic and emotional influences.

Hormones of the digestive tract. Digestive functions are controlled not only by nerve impulses but also by humoral factors, and most of the digestive functions have a double control, nervous and humoral. Complete denervation is usually followed by only transitory disturbances, which do not affect digestive functions sufficiently to cause serious hindrance to digestion. Nervous control is preponderant in the initial stages of digestion, but it diminishes and humoral factors become more important in the further stages. Salivary secretion is almost exclusively dependent on the nervous system; both nervous and humoral factors exert their effects on the stomach; the pancreas is mainly under the control of humoral influences; in the large intestine, nervous control is again preponderant.

Digestive hormones are among the most important humoral factors that control digestion. Hormones are specific substances secreted by an organ or tissue and carried by the blood to the organ or tissue on which they exert their specific activity. Digestive hormones are produced in the gastrointestinal mucosa in response to specific stimuli.

There are certain differences between digestive hormones and those secreted by the endocrine glands. The endocrine glands constitute an interrelated system; digestive hormones are an independent system which is not influenced by, and has no influence on, the endocrine system. The only known factors which regulate the activity of the digestive hormones are substances in the gastrointestinal tract (food, products of digestion, secretions of the mucosa, etc.). When the adequate stimulus is applied, after a latent period, the hormone is released, and when the stimulus ceases to be active, the hormone ceases to be secreted.

The extraction from a segment of gastrointestinal mucosa of a substance which exerts an effect on some aspect of digestive secretion or motility is not sufficient evidence for attributing hormonal activity to this substance. The following conditions must first be fulfilled:

1. The substance must be released by the effect of specific stimuli, acting on a definite segment of the gastrointestinal mucosa.
2. The substance must exert a specific effect on a certain organ or tissue and not on others.
3. This effect must be produced by the release of the substance from the mucosa into the blood stream.
4. The substance must be extracted and purified sufficiently so as to eliminate other active substances (acetylcholine, histamine, etc.).
5. Experimental evidence must be obtained that in physiologic conditions a certain digestive function is under hormonal control. Several digestive hormones have been described; for some of them, however, conclusive evidence that they play a part in the physiologic control of digestion has not yet been obtained.

The following are the main digestive hormones:

Gastrin (Edkins[1]) is secreted by the gastric mucosa in response to mechanical stimuli (distention of the stomach) and chemical stimuli (products of partial protein digestion, meat extract, etc.); it stimulates the secretion of HCl by the gastric glands.

Secretin (Bayliss and Starling[2]) is released by the mucosa of the upper part of the small intestine when stimulated by certain chemical agents (HCl, etc.); it provokes the secretion of pancreatic juice.

Pancreozymine (Harper and Raper[1]) is released by the intestinal mucosa stimulated by chemical agents (soaps, peptone, starch, etc.); it stimulates the secretion of pancreatic enzymes.

Cholecystokinin (Ivy and Oldberg[2]) is released by the mucosa of the upper part of the small intestine stimulated by certain chemical agents (fats, fatty acids, HCl, peptone, etc.); it provokes contraction and emptying of the gall bladder.

Enterogastrone (Kosaka and Lim[3]) is released by the mucosa of the upper part of the small intestine stimulated by fat and sugars; it inhibits gastric secretion and motility.

Enterocrinin (Nasset[4]) is released by the intestinal mucosa in response to the ingestion of a mixed meal; it increases the volume and concentration of intestinal juice.

Villikinin (Kokas and Ludany[5]) is released by the duodenal mucosa in response to HCl; it increases motility of intestinal villi.

Duocrinin (Grossman[6]) is released by the intestinal mucosa stimulated by certain foods (mixed meal, dextrose, cottonseed oil, etc.); it stimulates secretion of the Brünner glands in the duodenum.

It is doubtful that other substances can be considered as hormones, *e.g.*, *urogastrone*, extracted from urine, which depresses gastric motility and secretion, and *anthelone*, extracted from urine and intestinal mucosa, which has antiulcer activity in dogs with a Mann-Williamson operation.

ABSORPTION

Absorption consists in the passage into the organism of substances coming from the environment. The skin does not absorb water or substances dissolved in water. Gases and volatile substances (iodine, methyl salicylate, etc.) and fat-soluble substances (Hg, steroids) are absorbed through the skin, a fact that has important applications in therapeutics. The linings of the body cavities (pleura, peritoneum, etc.)

and mucosae (conjunctiva, respiratory tract, sublingual mucosa, etc.) rapidly absorb substances dissolved in water, oil, or glycols.

Absorption from the digestive tract. The purpose of digestion is to convert ingested foodstuffs by a long series of chemical reactions into simple, easily soluble substances that can be readily absorbed. The passage of these substances into the cells lining the digestive tract and their transfer to the internal media are accomplished by physicochemical processes that are still not completely understood. The problem of digestive absorption is part of the problem of cellular permeability which is as yet unsolved.

The stomach can absorb fairly rapidly alcohol and other substances[1] such as alkaloids, salts, acids, and the products of protein digestion; it absorbs little or no sugar, fat, or carbohydrate. The stomach is of only secondary importance in the absorption of foodstuffs.

The large intestine can absorb water and certain substances in solution such as salts, glucose, etc.

The greater part of digestive absorption takes place in the small intestine. It is therefore important to study the structure of the large mucous surface of this part of the digestive tract.

The intestinal villi facilitate absorption considerably. Each square millimeter of intestine represents an absorbing surface of 3 to 18 sq. mm. The villi are made up of a supporting frame of connective tissue which contains a few muscle fibers. A small arteriole penetrates into each villus and ends in a capillary plexus drained by one or two venules. There is also a capillary lymph vessel (lacteal). The lacteal vessel opens into a lymphatic network provided with a system of valves that prevents the lymph from returning to the villi. The fingerlike process is covered by a layer of cylindrical epithelial cells with a striated border, lying on a basal membrane; these are the absorbing cells. A few cuplike cells that secrete mucus are interspersed in the columnar epithelium. Between the bases of the villi, the crypts or Lieberkühn's glands open into the intestine. There are four types of cell in these glands: cylindrical epithelial cells, caliciform cells (which secrete mucus), the cells of Paneth, and granular argentophil cells.

Fibers from the muscularis mucosa are inserted on the wall of the lymph vessel of the villi and on the basal membrane. Contraction of these fibers empties the lymph vessels, and their relaxation produces a negative pressure within these vessels which helps absorption from the intestine.[1]

The intestinal villi have a pistonlike movement; they shorten without any considerable thickening, and then gradually regain their length. The effect of these movements on absorption is not well known. The contraction of the smooth-muscle fibers in the villi is responsible for their movement. The fibers respond to stimulation of Meissner's plexus, and it seems that there is a hormone, known as "villikinin,"[2] secreted by the intestinal mucosa, which is the normal stimulus for the contraction of the villi.

Absorption of water and watery solutions. Water and salts are absorbed by the cells covering the villi and apparently pass directly into the blood capillaries and thence to the portal vein. It is possible, however, that these substances pass first into the lymph vessel and that in the submucosa, where lymph vessels and veins are in close contact, an exchange between lymph and plasma can take place. At any rate, water and salts must be taken up mainly by the blood stream, for the ingestion of large amounts of water can dilute the blood, but the absorption of saline solutions does not increase the lymph flow in the thoracic duct.

An important question is whether the process of absorption through the epithelial cells of the intestinal mucosa is exclusively a physical one of osmosis, diffusion, adsorption, imbibition, filtration, etc., or a physiologic process in which the cells take an active part. This active participation of the cells might consist in the selective absorption of those substances most urgently needed by the organism, or it might consist simply in the motor mechanism described above.

In the small intestine osmosis and diffusion take place. When a concentrated NaCl solution is injected into an intestinal loop previously isolated from the rest of the bowel, the loop fills with fluid because of the high osmotic pressure of its contents, and NaCl passes into the blood according to the laws of diffusion. Nevertheless the difference in concentration of the intes-

tinal contents on one side, and the blood or lymph on the other, is not enough to explain absorption in all cases. Heidenhain[1] injected a dog's own plasma into an isolated loop of its intestine and observed that the plasma was completely reabsorbed; in this case there were no differences in concentration to explain absorption; therefore, osmosis is not the main factor in the absorption of water and electrolytes, and other active processes must take place in the intestinal epithelium. More recent experiments, in which radioactive isotopes and heavy water have been used, have confirmed this conclusion.[2] If isotonic solutions of NaCl and Na_2SO_4 are injected into the isolated loop, the NaCl is completely absorbed while the sulfate remains in the bowel. According to the laws of diffusion it would be expected that chloride, of which there is 0.6 per cent in the blood, would be absorbed slowly, while the sulfate, of which there is very little in the blood, would be rapidly absorbed.

The velocity of absorption by the intestine of many substances (*e.g.*, glucose) remains constant throughout the whole process; if absorption took place by diffusion and osmosis, the velocity would decrease as the concentration of the substance in the intestine diminished. When the cells of the mucosa are intoxicated with cyanide or fluoride or there is intense anemia, the mucosa behaves as an organic but lifeless membrane. Therefore in the passage of water and salts from the intestine to the blood, processes dependent on the integrity of the metabolism of the cell play a part. What these processes consist in, and what forces take part in them, are problems still unsolved; probably they are similar to those by means of which glomerular filtrate is reabsorbed by the renal tubes.

Evidence has been given of the selective absorption of several substances. For example, glucose and galactose are absorbed more rapidly than other carbohydrates. Phosphorylation, taking place in the cells of the mucosa, has been considered as the cause of this selective absorption. Phosphorylation consists in the union of the carbohydrate and phosphate to form hexosephosphates. Monoiodacetic acid inhibits phosphorylation and suppresses the selective absorption of monosaccharides.

[1] Heidenhain, R., *Pflüger's Arch. f. d. ges. Physiol.*, p. 579, 1894.

[2] Visscher, M. B., *et al.*, *Am. J. Physiol.*, **142**, 550, 1944; **144**, 457, 1945.

Another problem still under discussion is whether the absorbed substances pass from the lumen of the intestine into the blood through the cells or between them. The epithelial cells, like other cells in the organism, are covered by a membrane that is permeable only to fat-soluble substances. Therefore water, salts, carbohydrates, and other substances not soluble in fats would have to pass between the cells. Experiments with dyes, soluble and insoluble in fats, seem to confirm this assertion. It is also possible that the lipids in the external layer of the epithelium act as a protective mechanism and that the properties of the membrane are modified by the needs of the organism.

Absorption of proteins.[1] The products of the digestion of protein are absorbed exclusively by the small intestine.

Observations made on animals with fistulas at different levels of the small intestine show that ingested protein is completely or almost completely changed by the action of the digestive enzymes into amino acids or very simple peptides.

During the period of absorption there is a slight and transitory increase in the amino-acid concentration of the blood. The lymph vessels cannot be of much importance in the absorption of protein, as they can be totally suppressed without causing serious interference in protein absorption.

The fact that an organism can be maintained in protein equilibrium by intravenous injection of amino acids, or of the products obtained by digesting proteins *in vitro*, gives further support to the contention that proteins are absorbed as amino acids. This procedure is used in the feeding of patients whom it is not possible to feed by mouth.

Nevertheless, immunologic methods that allow the detection of very small amounts of specific proteins have been used to show that normally in many subjects certain proteins can pass unaltered from the intestine into the blood. This fact is of importance, inasmuch as it proves the possibility of sensitization to ingested proteins (alimentary allergy), but it does not modify substantially the assertion that proteins are absorbed after they have been disintegrated into their component amino acids.

Absorption of fats.[2] Neutral fats in the food are split up into their components—glycerol and

[1] See Chap. 43, Protein Metabolism.

[2] See Chap. 42, Fat Metabolism.

fatty acids—by the action of the digestive lipases, especially of pancreatic lipase. Examination of the intestinal contents at different levels has shown that, as the distance from the stomach increases, the proportion of fatty acids to fats increases. The fatty acids form, with the bile salts, diffusible and water-soluble sodium soaps. These soaps facilitate the emulsification of fats, which therefore become more susceptible to the action of enzymes. Soaps are unstable because of the slight acidity of the intestinal contents. Monoglycerides also facilitate fine emulsification of fats.

Glycerol and fatty acids are taken up by the epithelial cells, where they again combine to form fats, which pass into the lymphatics. After a meal containing fats the lymphatics in the mesentery are filled with a milklike fluid—the chyle—the opacity of which is due to small particles of 0.05 to 0.1 μ, called chylomicrons. The milky fluid is an emulsion of neutral fats. After a fatty meal, lymph loaded with fat flows in increased amount from the thoracic duct, and the fat content of the blood plasma is increased. The mechanism of the absorption of fats will be discussed when considering fat metabolism (Chap. 42).

HUNGER AND APPETITE

Cannon and Washburn[1] demonstrated that the painful sensations of hunger coincide with strong peristalsis in the body of the stomach. Carlson and his associates investigated factors that awake or inhibit the painful contractions. The theory thus arose that hunger is essentially a painful gastric sensation. The behavior of men and animals after gastrectomy or denervation of the stomach, the fact that insulin increases the ingestion of food in animals with a denervated stomach whereas sympathicomimetic amines decrease it, and other observations show that hunger is something more than painful gastric contractions.

Body weight is maintained constant during long periods in adult life, in spite of considerable variations in the consumption of energy; therefore the ingestion of food is adjusted with great accuracy to the needs of the organism. "The hunger state is the physiological state resulting from the privation of food of a specific or general type and abolished by the ingestion of these foods" (Ivy). This is a primitive, nonconditioned state, made evident by (*a*) special behavior, *e.g.*, increased motility; and (*b*) hunger sensations, such as general weakness, tiredness, nausea, irritability, headache, sensation of emptiness or tension, and pain in the epigastrium.[1]

[1] Cannon, W. B., and A. L. Washburn, *Am. J. Physiol.*, **29**, 441, 1912.

After experience has taught man and animals that ingestion of food suppresses the disagreeable sensations and behavior of hunger, conditioned cortical reactions increase the complexity of the response. Hunger sensations give rise to the desire for food or *appetite*, and hunger behavior is incorporated into an acquired *appetitive behavior* (Janowitz and Grossman). The ingestion of food suppresses appetitive behavior, and the desire for food ceases (satiety or physiologic anorexia).

The ingestion of food is normally controlled so that a stable equilibrium is maintained between the intake and output of energy, and the body weight remains fairly constant in spite of wide variations in the diet, the work performed, and the temperature of the environment. There are regulatory mechanisms in the central nervous system which control this adjustment.[2] In dogs and other animals the destruction of part of the ventromedial nucleus of the hypothalamus provokes hyperphagia and obesity.[3] Destruction of the lateral aspect of the lateral region of the hypothalamus produces complete anorexia in cats and rats.[4] This part of the hypothalamus acts as a feeding center, normally inhibited by those parts of the ventromedial nucleus the destruction of which causes hyperphagia. Evidence has been brought forward of the existence in the hypothalamus of chemoreceptors sensitive to changes in the blood-sugar level, and to other humoral factors.[5]

Specific appetite.[6] The constancy of the internal environment (homeostasis) is maintained by a series of physiologic and chemical

regulatory mechanisms. Numerous examples of coordinated processes that regulate the blood pressure, the blood sugar, the acid-base equilibrium, etc., can be brought forward; besides these, the organism as a whole presents reactions that contribute to maintain homeostasis. These are reactions of behavior that have been studied systematically by Richter, corroborating and extending previous isolated observations.

The existence of this type of regulation, in which the whole organism takes part, was demonstrated by Richter in animals after a disturbance in the equilibriums of their internal environment had been induced by the extirpation of an organ of fundamental importance for homeostasis. For example, removal of the adrenal glands in rats produces a disturbance in sodium metabolism; the animal loses great quantities of sodium in the urine and the internal environment is seriously upset. If the animals are given water and an ordinary diet, they die in 8 to 15 days. If on the other hand they are also given access to a 3 per cent solution of NaCl, they will drink enough of this saline solution to keep alive and without symptoms of adrenal insufficiency.

Another example is given by parathyroidectomized rats, in which there is a serious disturbance in calcium metabolism. These animals are put into a cage where there are two graduated drinking flasks, one with distilled water and the other with a 2.4 per cent calcium lactate solution, and the amount of fluid drunk from each flask is measured daily. Immediately after parathyroidectomy, the animals drink more calcium lactate and thus keep alive and free from symptoms of tetany. If parathyroid insufficiency is now treated in these animals by the administration of a drug (dihydrotachisterol), or by grafting a parathyroid in the anterior chamber of the eye, the animals will reduce the amount of calcium lactate they drink to that taken before parathyroidectomy (Fig. 160).

FIG. 160. Specific appetite for calcium lactate. Parathyroidectomy increases the ingestion of calcium, and parathyroid implantation decreases it. (*Richter, C. P., Harvey Lect., vol. 38, p. 63, 1942–1943.*)

The capacity of rats to select their diet goes even further. Animals were put in cages with several drinking flasks and feeding troughs, in which measured amounts of protein, carbohydrate, fat, vitamins, and several salt solutions were placed. The rats chose for themselves a complete diet which allowed them to grow at the same rate as the controls fed on a standard diet. Pancreatectomized rats spontaneously re-

fused carbohydrate and fed principally on protein and fat. When vitamin B_1 (thiamine, aneurine) was withheld, the animals diminished the ingestion of carbohydrate and increased that of fat.

These examples are enough to show the practical importance of a method that can be used in many ways and that has already been admirably applied by Richter and his collaborators. The mechanism of these self-regulatory functions is still incompletely understood.

CHAPTER 36

The Secretion of Saliva. Mastication and Deglutition

THE PROCESS OF digestion begins in the mouth where food is soaked in saliva, is broken up and crushed by mastication, and after the bolus has been formed, is swallowed, *i.e.*, passed into the pharynx and through the esophagus to the stomach (deglutition).

THE SECRETION OF SALIVA

Saliva is secreted by the three pairs of salivary glands, the parotid, submaxillary, and sublingual glands, the names of which indicate approximately their position. There are also small "buccal" glands situated in the mucosa of the mouth. The principal salivary glands pour their secretions into the mouth by means of well-differentiated ducts, which can be catheterized so as to collect the secretions. The ducts of the submaxillary and sublingual glands end in the floor of the mouth, under the tongue; the parotid ducts end on the side wall of the mouth on each side.

Methods of study. There are two ways in which the saliva can be studied: (*a*) the total, mixed saliva can be collected by voluntary or forced evacuation of the mouth (spitting) or by means of a fistula of the esophagus; (*b*) the saliva secreted by each gland can be obtained by catheterization of the respective duct or from a fistula produced experimentally[1] (Fig. 161) or pathologically.

Types of gland. Three types of gland can be distinguished according to their structure: mucous, serous, and mixed.

In the mucous glands the cells lining the walls of the alveoli form a single layer on the basal membrane, and the cytoplasm contains numerous droplets of mucinogen. The serous glands have smaller cells, with a deeply staining nucleus and a granular cytoplasm (zymogen granules). In man the buccal glands are of both types; the parotid is a typical serous gland; the submaxillary and sublingual glands are mixed, but serous cells predominate in the former and mucous cells in the latter.
FIG. 161. Parotid fistula in the dog. (*Le Play, "Technique opératoire physiologique," Masson et Cie, Paris, 1912.*)

Types of saliva. The secretion of the mucous glands is viscous, because of its high mucin content. In man it also contains an amylase, ptyalin.

[1] LE PLAY, "Technique opératoire physiologique," Masson et Cie, Paris, 1912, pp. 72 and 79.

Serous glands, *e.g.*, the parotid, secrete a fluid saliva, with almost no mucin; on the other hand the ptyalin content of the parotid secretion is about four times that of the mucous glands.

Stimulation of salivary secretion. In man saliva is secreted continuously (saliva of fasting or rest); the amount secreted is approximately 15 cc. per hr. With adequate stimuli this amount can be rapidly and considerably increased. The quantity and quality of the saliva vary with the nature of the stimulus. The amount secreted in 24 hr. ranges from 600 to 1,500 cc. During sleep almost no saliva is secreted. An increase in salivary secretion is obtained by applying thermal (heat), mechanical (chewing sand, stones, paraffin, rubber, etc.), or chemical stimuli to the mucosa of the mouth. Among the chemical stimuli the most efficient are those provoking gustatory sensations. Substances not actually foods, such as acids, alkalis, bitters, etc., which have a strong disagreeable taste cause abundant secretion of saliva. Dryness of the mouth or irritation of the mucosa by defective teeth or badly placed dental fixtures can also provoke abundant salivary secretion. Distention of the esophagus and stimulation of the gastric mucosa by food or irritating substances stimulate the secretion of saliva. The flow of saliva increases whenever there is an increase in the acidity of the blood.[1]

Conditioned reflexes produce salivary secretion, as when the "mouth waters" at the sight or thought of food. In an animal with a salivary fistula, the flow of saliva produced by the introduction into the mouth of a savory substance or of food can be measured. This secretion is the result of an inborn reflex, which has its center in the medulla and takes place without the intervention of the cerebral cortex. If the introduction of a salivary stimulus into the mouth is repeatedly associated with the application of another stimulus, incapable of producing salivary secretion per se, *e.g.*, the ringing of a bell, after several repetitions salivary secretion will be provoked by just ringing the bell, even if no food is given. The animal thus acquires a new reflex, called by Pavlov a "conditioned reflex." A stimulus originally unefficacious takes on by association the properties of the stimulus that naturally produces salivary secretion. Such a "conditioned reflex" occurs only if the corresponding parts of the cerebral cortex remain intact.

[1] Brassfield, C. R., *Am. J. Physiol.*, **144**, 43, 1945.

Reflex nature of salivary secretion. The stimuli mentioned above produce salivary flow by reflex action. The afferent paths are the sensory nerves of the mucosa of the mouth. The glossopharyngeal nerve innervates the posterior third of the tongue; the anterior two-thirds and the tip of the tongue are innervated by the lingual nerve (the gustatory fibers being included in the chorda tympani).

The salivary center is situated in the reticular formation of the fourth ventricle, between the nucleus of the facial nerve and Deiter's nucleus. The cephalic part of this nucleus is connected with the submaxillary glands, and the caudal part with the parotid glands.[1] Salivary flow can be produced by stimulation of the cerebral cortex, but section of the brain stem above the pons does not suppress the normal inborn salivary reflexes; therefore the most important center is the one situated in the medulla and pons.

The salivary glands are innervated by the visceral nervous system, each gland receiving both sympathetic and parasympathetic fibers (Fig. 162).

The parasympathetic fibers of the submaxillary and sublingual glands are conveyed by the chorda tympani; they come from the salivary center in the pons, branch off from the facial nerve with the chorda tympani, and eventually join the lingual nerve. In the floor of the mouth the preganglionic parasympathetic fibers branch off from the lingual nerve going toward the submaxillary gland and ending in a small ganglion situated in the hilum of the submaxillary gland. Fine unmyelinated postganglionic secretory fibers go from this ganglion and end in the gland. The postganglionic fibers for the sublingual gland also arise in the submaxillary ganglion.

The parasympathetic fibers for the parotid have their origin in the medulla and are incorporated into the glossopharyngeal nerve, passing to its tympanic branch or nerve of Jacobson, and thence through the small superficial petrosal nerve to the otic ganglion. The postganglionic fibers commencing in this ganglion join the auriculotemporal nerve, a branch of the inferior maxillary division of the fifth nerve.

The sympathetic fibers for the three salivary glands leave the spinal cord in the second to the

[1] Wang, S. C., *J. Neurophysiol.*, **6**, 195, 1943.
Fig. 162. Innervation of the salivary glands. (*Redrawn from Müller, with modifications.*)

sixth dorsal roots. They end at the superior cervical ganglion, whence the postganglionic fibers follow the branches of the external carotid to the respective salivary gland.

The parasympathetic nerves are vasodilator and the sympathetic nerves are vasoconstrictor.

Electrical stimulation of the secretory nerves. Electrical stimulation of the chorda tympani provokes in a few seconds abundant salivary secretion by the submaxillary gland. The concentration of the saliva and the quantity secreted depend to some extent on the intensity of the current used for stimulation. An increase in the strength of the stimulus provokes a more abundant secretion, not only of fluid but also of the organic and inorganic components of saliva. The vessels of the gland dilate, the blood flow increases from four to eight times, and the oxygen consumption increases from two to three times.

Stimulation of the auriculotemporal nerve produces similar effects in the parotid.

Stimulation of the sympathetic nerves produces the secretion by the submaxillary and sublingual glands of a small quantity of viscous saliva, but no secretion in the parotid gland. A marked vasoconstriction is provoked in all three glands.

The action of the parasympathetic is due to the liberation of acetylcholine in the nerve endings; injection of acetylcholine produces exactly the same effect as stimulation of the parasympathetic nerve. The effects of acetylcholine and stimulation of the parasympathetic secretory nerves are reinforced by eserine and suppressed by atropine. Therefore the parasympathetic fibers of the salivary glands are cholinergic. Pilocarpine also provokes profuse salivation, but the saliva secreted is not identical to that secreted as a result of acetylcholine injection or stimulation of the parasympathetic.

The effect of sympathetic stimulation is due to the release of a chemical mediator. This is demonstrated by the following experiment: If the cervical sympathetic is stimulated after cutting all its branches except those to the submaxillary gland, a substance appears in the blood which provokes contraction of the nictitating membrane. This effect is potentiated by cocaine.

The nature of salivary secretion. *Phenomena accompanying glandular activity.* We have seen that stimulation of the parasympathetic produces an intense vasodilatation of the salivary glands and that the blood flow becomes four to eight times greater. The increase in the blood flow occurs even if the secretory action is inhibited by atropine. The volume of the gland increases, and an electrical variation can be registered. The oxygen consumption is increased; Barcroft found that from 0.25 cc. per min. it rose to 0.86 cc. per min. in the submaxillary gland of a small dog.

There are also *histologic changes* during activity. In the resting gland the cytoplasm is full of zymogen or mucinogen granules. As the gland becomes active the granules diminish until they are reduced to a few in the pole of the cell nearest the duct. These granules are usually considered as made up of the precursors of ptyalin in the serous cells and mucin in the mucous cells.

As far back as 1851, Ludwig[1] saw that the electrical stimulation of the chorda tympani increased salivary flow, and his experiments demonstrated that this effect was not due merely to filtration of water and salts from the blood through the epithelium of the glands.

Heidenhain was able to distinguish two main processes: (*a*) the passage of water and crystalloids from the blood through the capillary wall and glandular cells into the ducts of the gland, and (*b*) the discharge of organic substances secreted and stored in the gland during the periods of rest. The mechanisms of these processes are probably complex. Nerve impulses and humoral factors may give rise to osmotic forces within the cells, or changes in permeability, which cause the passage of water and crystalloids into the duct. According to Heidenhain, nerve impulses produce "trophic" effects which convert organic colloids stored in the gland into more soluble substances, which are then released into the ducts.

The salivary glandular cells undoubtedly consume energy not only for the synthesis of their secretory products but also for osmotic and mechanic work, because stimulation of their nerves, with the release of chemical mediators, increases the activity of the cells. Acetylcholine increases the O_2 consumption of surviving slices of salivary-gland tissue *in vitro*,[1] a fact which has been interpreted as evidence that the chemical mediator accelerates intracellular metabolic processes. The sources of energy in the salivary gland are apparently similar to those of muscle.[2]

Regulation of salivary secretion. Heidenhain's experiments on electric stimulation of the salivary nerves led him to maintain there were two types of nerve fibers, secretory and trophic. Secretory fibers predominate in the parasympathetic and trophic fibers in the sympathetic, and each cell is innervated by both kinds of fiber. The vasomotor effects exerted by the nerves are relatively independent of their simultaneous secretory or trophic activity.

This theory was almost universally accepted, in spite of the objections brought against it by Langley and Carlson and their associates. Babkin has shown that the trophic (ecbolic) effect is due not to the sympathetic but to the parasympathetic (see page 327). The secretion of a salivary gland in which the sympathetic innervation has been eliminated varies in volume and

[1] Ludwig, C., *Zeit. f. Rat. Med., n.F.*, **1**, 255, 1851.

[2] Northrup, D., *Am. J. Physiol.*, **114**, 46, 1935.

amount of organic substances according to the strength of the stimulus applied to the remaining parasympathetic fibers, or according to the stimulus (food, sapid substances) applied in the mouth. These and other results obtained by Baxter[1] and other associates of Babkin led the latter to a new conception of how salivary secretion is regulated, which may be extended to all the digestive glands. A gland does not function as a single entity but is made up of different epithelial components which form distinct functional units. Each one of these units contributes to the formation of the final product in different ways varying with the nerve or humoral stimulation to which they have been submitted.

Histophysiological studies have brought forth evidence that the sympathetic and parasympathetic innervate different groups of cells. Stormont[2] has shown that in the submaxillary gland of the rabbit the chorda tympani innervates the blood vessels, the intercalated ducts, and the homeochrome serous cells. The sympathetic innervates the blood vessels and the tropochrome serous cells. Rawlinson[3] observed the histologic changes provoked by nerve stimulation in the submaxillary gland of the cat. Stimulation of the parasympathetic (chorda tympani) caused changes in the mucous cells, and sympathetic stimulation (cervical sympathetic or intravenous injection of adrenaline) caused changes in the serous (semilunar) cells.

Paralytic secretion. Claude Bernard[4] observed that 2 to 3 days after the chorda tympani had been cut the submaxillary gland began to secrete continuously small amounts of fluid, turbid saliva, which increased gradually, reaching a maximum in 7 to 10 days, and persisted for several weeks. The glands did not respond to reflex stimulation and diminished progressively in size. Section of the sympathetic was not followed by "paralytic secretion." Bernard interpreted these facts as evidence of an inhibitory effect of the nerves on salivary secretion. Heidenhain maintained that saliva retained in the glands after denervation stimulated the cells. Langley saw that stimulation of the peripheral end of the chorda tympani, several weeks after

it had been cut, increased the paralytic secretion of the gland. He attributed this to the existence of ganglionic neurons in the nerve and in the gland which were permanently active.

Histological studies[1] of the submaxillary gland after section of the chorda tympani have shown that the mucous cells have the aspect typical of the resting condition and that the serous (semilunar) cells appear to be active. Rawlinson, as was mentioned above, also saw that sympathetic stimulation and intravenous injection of adrenaline increase the activity of the semilunar cells. According to Babkin, paralytic secretion is further evidence that the sympathetic and parasympathetic innervate different groups of cells. Paralytic secretion would, therefore, be due not to the denervated cells but to others which are innervated by fibers not included in the chorda tympani.

Emmelin[2] attributes paralytic secretion, not to spontaneous activity of the cells or their innervation, but to the action of adrenaline or noradrenaline on secretory cells sensitized to these substances by section of the chorda tympani. Babkin and his associates had already observed that parasympathetic denervation sensitized the gland to adrenaline and to sympathetic stimulation. According to Emmelin paralytic secretion is not continuous, but provoked by experimental procedures which cause the discharge of impulses in the sympathetic fibers of the gland, or increase the concentration of adrenaline or noradrenaline in the blood.

Augmented secretion. Stimulation of the chorda tympani increases the response to subsequent stimulation of the same nerve or of the sympathetic.[3] This "augmented secretion"[4] is also observed when sympathetic stimulation precedes sympathetic or parasympathetic stimulation. After stimulation of the chorda tympani possibly the chemical mediator (acetylcholine) persists for a time and adds its effect to that of acetylcholine released by a second period of stimulation. There is also evidence that previous activity of the mucous cells increases the excitability of the semilunar cells, a fact that would explain augmented secretion in response to

sympathetic stimulation following stimulation of the chorda tympani.

Changes in saliva in relation to the intensity of the stimulus. On increasing the strength of the electrical stimulus, the amount of saliva secreted and the salt concentration increase. At first the concentration of protein also increases, but later, when the gland is fatigued, it diminishes. Potassium concentration in saliva varies independently of the rate of secretion.

The saliva secreted by the submaxillary gland due to sympathetic stimulation has a higher concentration in K, Ca, mucin, and albumin, and a lower concentration in Na and Cl, than parasympathetic saliva obtained by stimulation of the chorda tympani. These nerves must be stimulated repeatedly to obtain an abundant flow; there seems to be an optimum frequency, which for the chorda tympani of the cat is about nine stimuli per second.

Changes in saliva in relation to the nature of the stimulus. Pavlov called attention to changes in quality and quantity of saliva according to the nature of the substance introduced into the mouth and acting as a stimulus. Raw meat produces a less abundant flow than meat powder. Smooth stones do not provoke salivary secretion, while sand is a potent stimulus. In the case of meat powder abundant salivation facilitates the rapid formation of the bolus, while in the case of sand its removal from the mouth is hastened. Acids provoke the secretion of saliva rich in proteins that act as buffers, so that the excessive acidity tends to be neutralized. Edible substances, such as meat and milk, stimulate the secretion of saliva with a high concentration of organic substances (ptyalin, mucin, etc.) especially adapted to lubricate the food (lubricant saliva). Dry substances (meat powder, sand) produce an abundant flow of fluid saliva (diluting or solvent action).

The mechanism by which this fine quantitative and qualitative adaptation to the nature of the stimulus takes place is as yet unknown.

FUNCTIONS OF SALIVA

Saliva has many important functions, but is not essential to life in man; cases have been described of congenital absence of the salivary gland (xerostomia or aptyalism) in which there was no serious disturbance in digestion. The dog and the rabbit survive extirpation of the salivary glands and remain apparently normal. On the other hand if both parotid ducts are fistulized in a horse, the animal has difficulty in chewing and swallowing, it eats less and more slowly and eventually can become seriously ill. Removal of the salivary glands in the newborn rat disturbs swallowing to such an extent that the animal dies of starvation. The suppression of the flow from both parotids in the sheep produces after a time a progressive state of undernourishment which ends with the death of the animal. This has been attributed to the lack of alkali normally secreted in the parotidean saliva, which is needed to neutralize acids formed in the animal's stomach.

The principal functions of saliva are (*a*) dilution and lubrication of foods, so that chewing and swallowing are facilitated; (*b*) the solution of sapid substances, so they can stimulate the taste buds; (*c*) moistening and cleaning of the mouth and protection of the teeth; (*d*) the commencement of the digestion of starch.

Claude Bernard[1] attributed to the saliva of each gland a special function: submaxillary saliva is stimulated principally by sapid substances and is the saliva of taste; parotidean saliva serves to moisten the mouth and foodstuffs and thus facilitates mastication; sublingual saliva lubricates the food and favors swallowing. This opinion has been confirmed to a great extent.

Imbibition and lubrication of food. One of the most important functions of saliva is to facilitate chewing and swallowing. Saliva moistens dry foodstuffs and thus furthers mastication and the formation of the bolus, covering it with a lubricant layer which helps it to be swallowed.

Action on taste. A sapid substance must be dissolved to act on the taste buds; *e.g.*, quinine, a very bitter but only slightly soluble substance, when placed on the tongue in the form of powder has scarcely any taste. Saliva dissolves solid foods, which can then be tasted.

Lubricant action on the mucosa. Saliva lubricates the mucosa of the mouth and thus facilitates mastication and speech. Subjects suffering from aptyalism must frequently moisten their mouths with water. Public speakers sometimes have to sip water frequently to complement an insufficient salivary flow. Saliva also

[1] BERNARD, C., "Leçons de physiologie expérimentale," vol. 2, J. C. Baillière et fils, Paris, 1856.

protects the teeth; dental caries is common in cases of aptyalism.

Digestive function. Human saliva and that of some herbivora contain an amylase called ptyalin which accelerates the breakdown of starch and glycogen into maltose. Food remains but a short time in the mouth, so ptyalin could have but little effect on carbohydrate digestion, except for the fact that the saliva impregnates the whole bolus, and as the gastric juice takes some time to penetrate into its deeper layers, ptyalin can exercise its hydrolytic effect in the stomach. As the acidity increases, the action of ptyalin diminishes until it ceases completely.

Role of saliva in thirst. When there is a great loss of water (sweating, diarrhea, polyuria, hemorrhage, etc.), salivary secretion diminishes and can cease completely. The subsequent drying of the mouth is one of the principal factors of the sensation of thirst.

MASTICATION

The crushing and breaking up of the food begin in the mouth, by the combined action of the jaws and the teeth, the masticatory muscles, the tongue, and the cheeks.

The articulation of the lower jaw with the skull varies in different species according to their diet. In carnivora the condyle is firmly fixed in the cavity of the temporal bone; a strong joint with limited movements is thus formed. In ruminants there is a small condyle and a shallow glenoid cavity, which permits ample lateral movements. The disposition of the joint in rodents is such that it facilitates movements of projection and retraction of the jaw.

In man this joint is so formed that all kinds of movements can be executed. The muscles that move the jaw can be divided into those that raise it (elevators) and those that lower it (depressors). Each one of these muscles also projects or retracts the jaw, and by the combined action of several muscles lateral movements are performed. The following diagram shows the masticatory muscles and their functions:

Elevators..	Projectors...	Masseter Internal pterygoid
	Retractor...	Temporal
Depressors..	Projector....	External pterygoid
	Retractors...	Digastric Mylohyoid Geniohyoid

The combined action of the muscles of the tongue and cheeks is necessary for efficient mastication; these muscles act as the hopper in the mill (Cannon), placing the food between the dental arches. They also collect the particles of food into a mass or bolus, which is then swallowed.

Just as the temporomandibular joint varies in different species according to their diet, the teeth also vary; rodents have well-developed cutting incisors, carnivora have large canines which are used in tearing the food, and herbivora have large grinding molars. Sherrington[1] and Bremer[2] have studied a series of masticatory reflexes, which continue to take place in orderly sequence even after the cerebral cortex has been removed. Bremer has described three types of reflexes which are dependent on the place of excitation:

1. When the stimulus acts on the incisors, the anterior part of the masseter contracts and produces a series of rapid movements of the jaw. This is the gnawing reflex.
2. When the stimulus acts on the mucosa of the mouth anterior to the molars, ample rhythmic movements which raise and lower the jaw are produced. This is the vertical masticatory reflex.
3. When the stimulus acts on the mucosa near the molars, lateral movements of the jaw are provoked. This is the ruminatory reflex.

Sherrington has shown that stimulation of the mucosa of the mouth by the bolus reflexly depresses the jaw by inhibiting the muscles that raise it. This is followed by a rebound (see Chap. 70), in which these same muscles contract and sharply close the mouth. These movements are repeated rhythmically.

The centers of the masticatory reflexes are situated in the pons and the medulla.

Mastication crushes the food and facilitates its mixture with saliva and other digestive juices. Mastication also helps to stimulate the secretion of saliva.

Insufficient mastication does not seem to have any appreciable effect on the digestion and absorption of food. Nevertheless adequate chewing favors the complete digestion of foodstuffs that contain cellulose.

DEGLUTITION (THE ACT OF SWALLOWING)

The passage of food from the mouth to the stomach is called deglutition.

Methods of study. Several methods have been used to study the act of swallowing in both man and animal. Interesting data have been given by simple observation, especially in cases with surgical or accidental injuries; by the introduction of balloons for registering the variations in pressure; and by auscultation and registration of the sounds produced in swallowing. Observation by means of x-rays is undoubtedly the best method for the study of deglutition.

FIG. 163. X-ray diagrams of the stages in swallowing a liquid. At the beginning of ingestion the tip of the tongue is depressed and the liquid accumulates between the tongue and the dental arches (*a*). Next the tip of the tongue rises and the back part of the tongue is depressed (*b*); the liquid thus runs backward on an inclined plane (*c*). Finally the posterior part of the tongue is sharply drawn upward and backward, sending the liquid into the pharynx (*d*) and (*e*). (*Mosher, H. P., Laryngoscope, vol. 37, p. 235, 1927.*)

Description of the act of swallowing. Since Magendie[1] made his fundamental study of deglutition, it is customary to consider three stages in this act: (*a*) the first stage, which takes place in the mouth; (*b*) the second, in the pharynx; (*c*) the third, in the esophagus.

The first stage is under voluntary control. The soft mass of food, already chewed and mixed with saliva, or the liquids that have been taken into the mouth are placed between the tip of the tongue and the incisors. From there they pass to a hollow formed by the dorsum of the tongue covered by the palate. The tip of the tongue is then raised and pressed against the palate and the upper dental arch; the base of the tongue is depressed. Next the whole anterior part of the tongue is raised against the palate so that the bolus slides backward on an inclined plane. Finally the back of the tongue is sharply moved upward and backward, pushing the bolus into the pharynx (Fig. 163). The contraction of the mylohyoid muscles is the most important movement in this stage; the styloglossi and the glossopalatini assist in drawing the tongue backward.

The second stage in deglutition commences with the arrival of the bolus to the space between the base of the tongue and the posterior wall of the pharynx (Fig. 164). This stage and the following one are no longer under voluntary control, but are purely reflex. The stimuli act on the nerve endings in the mucosa of the pharynx, the epiglottis, and the soft palate; excitation is transmitted by the glossopharyngeal nerve to the center of deglutition in the medulla, where motor response is coordinated, and thus the complex act of swallowing continues.

The second stage is important because, as it passes through the pharynx, food crosses the

[1] MAGENDIE, F., "Précis élémentaire de physiologie," Paris, 1880.

respiratory path. Once in the pharynx the food mass as well as entering the esophagus might travel along one of three other ways: (*a*) it could go back into the mouth; (*b*) it could go up into the nasopharynx; (*c*) it could go down into the larynx. There are adequate mechanisms to stop the food from going in these directions.

Sustained contraction of the muscles responsible for the projection of the bolus into the pharynx prevents its return into the mouth. The contraction of the glossopalatini, which form the faucial pillars, narrows the isthmus of the fauces; the path back to the mouth is completely closed by the base of the tongue. Moreover contraction of the glossopalatini and the pharyngopalatini muscles produces a negative pressure in the pharynx and the esophagus,[1] while there is a positive pressure in the mouth; thus the progress of the bolus is further assisted.

The opening into the nasopharynx is closed by the contraction of the levator and tensor veli palatini and the muscles of the uvula, which raise the soft palate. These muscles also dilate the eustachian tubes and thus regulate the pressure in the middle ear. In cases of paralysis of these muscles (diphtheria, etc.) the act of swallowing is accompanied by partial regurgitation of liquid food into the nasal fossae.
FIG. 164. Stages of swallowing. *a*, when swallowing begins the bolus is pressed between the tongue and the palate; the larynx rises and the pharynx contracts. *b*, the bolus is tightly pressed against the hard palate; the soft palate rises and closes the nasopharynx; the larynx and the pharynx are closed. *c*, the pharynx begins to open, the lower part contracts and keeps the entrance to the larynx closed. *d*, the bolus enters the pharynx and slides over the epiglottis. *e*, larynx and pharynx return to their normal position as the bolus passes down the esophagus. (*Barclay, A. E., Brit. J. Radiol., vol. 3, p. 534, 1930.*)

The upper opening of the larynx is brought under the base of the tongue and closed by the epiglottis by the simultaneous contraction of the thyrohyoid and the suprahyoid muscles.

At the same time the vocal cords are brought together by contraction of the muscles attached to the arytenoid cartilages, which are drawn forward and rotated medially; thus the glottis is closed, and simultaneously the upper end of the esophagus is opened. The important part of this act is the raising of the pharynx. The epiglottis plays a minor part; its upper half can be destroyed without disturbing the act of swallow-

[1] BARCLAY, A. E., *Brit. J. Radiol.*, 3, 534, 1930.

ing. On the other hand, any lesion that hinders the movements of the larynx provokes serious difficulty in swallowing.

All the movements described take place very rapidly. They have been studied by roentgen-cinematography.[1] If the food swallowed is liquid or semiliquid, contraction of the mylohyoids, together with the contraction of other muscles in the floor of the mouth, projects it in a stream through the pharynx into the esophagus. If the food is solid or a soft paste, it also passes quickly through the pharynx, but in addition it is helped by the contraction of the constrictor muscles of the pharynx. The pharynx, which is initially contracted, relaxes suddenly and a negative pressure results; then the median and lower constrictors contract successively, impelling the food downward. At the beginning of the first stage a short inspiration (inspiration of swallowing) takes place, then there is complete apnea until the end of the second stage.

The third stage is the one during which the food progresses along the esophagus to the cardia. The second stage is completed in less than 1 sec.; the third stage is not so rapid. Fluids arrive at the cardia in 1 to 2 sec., and a soft well-lubricated bolus takes a few seconds.

In man progression of a solid or a semisolid bolus is assured by contractions of the esophagus in the form of peristaltic waves. Liquids pass rapidly down to the cardia while the esophagus is totally relaxed; for this reason corrosive fluids do not damage equally the whole length of the esophagus, but mainly its upper end and the part near the cardia.

Gravity helps the descent of fluids and semiliquid foods; but in man swallowing can be carried out even against the force of gravity. It is possible that the bolus is preceded by a wave of negative pressure, which helps to draw the food toward the cardia.

The nervous mechanism of deglutition. Reflex swallowing, *i.e.*, the second and third stages, commences with the application of stimuli on the nerve endings of the mucosa of the anterior and posterior pillars of the fauces, the uvula, the anterior aspect of the soft palate, the posterolateral wall of the lower pharynx, and the epiglottis. Local application of cocaine on these areas makes swallowing impossible for a time. The afferent paths of the reflex are the glossopharyngeal nerve, the upper laryngeal branch of the vagus, and the second division of the fifth cranial nerve.

The center of deglutition is situated on the floor of the fourth ventricle, a little above the respiratory center, in the neighborhood of the nucleus of the vagus. From this center impulses are sent to the motor centers that take part successively in the complex act of swallowing.

The efferent paths of this reflex go along the hypoglossal nerve to the muscles of the tongue—the trigeminal to the mylohyoid muscle; and the glossopharyngeal, the vagus, and the spinal accessory to the muscles of the pharynx, the larynx, and the esophagus. Once the reflex is started the whole series of movements takes place, including the peristaltic waves along the esophagus.

Mosso's[1] classic demonstration showed that the peristaltic waves depended on the integrity of the extrinsic innervation (the vagus nerve). He cut the esophagus into several segments and started a swallowing reflex by stimulating the pharynx. A peristaltic wave was thus started which traveled along the esophagus although there was no anatomical continuity of the gullet.

Section of the vagus provokes paralysis and dilatation of the esophagus and spasm of the cardiac sphincter. Food is not passed along to the stomach, but may go into the respiratory tubes and thus cause death. After some time the cardia relaxes and food can pass into the stomach.

The coordination of breathing and swallowing is of great importance. If breathing did not cease on swallowing, food might pass into the respiratory tubes, and this would have serious consequences. The apnea which commences at the beginning of the second stage of swallowing apparently is due to impulses carried by the glossopharyngeal nerve, because electrical stimulation of the central end of this nerve causes breathing to stop immediately.

THE CARDIA

Around the lower end of the esophagus there are muscular fibers which act as a sphincter. Usually these fibers are in a state of tonic contraction, but they relax on the arrival of food. Sometimes food is detained at the level of the sphincter until a peristaltic wave traveling along

[1] Ardran, G. M., and F. H. Kemp, *Proc. Roy. Soc. Med.*, **44**, 1038, 1951; Rushmer, R. F., and J. A. Hendron, *J. Applied Physiol.*, **3**, 622, 1951.

[1] Mosso, *Moleschotts Mitt.*, **11** (4), 23, 1874.

the esophagus passes it through the cardia. As long as the stomach contents are slightly alkaline, there is frequent regurgitation from the stomach through the cardia into the lower part of the esophagus. As the acidity of the stomach contents increases, regurgitation diminishes. This is due, according to Cannon, to a stronger tonic contraction of the cardiac sphincter provoked by gastric acidity.

The cardia is innervated by the vagus and the sympathetic nerves. Apparently both nerves have excitatory and inhibitory fibers. The effect of electrical stimulation of these nerves varies according to the previous state of the cardiac tonus; however the effect of the vagus is principally inhibitory and that of the sympathetic mainly excitatory. Bilateral cervical vagotomy disturbs the inhibitory mechanism and produces spasm of the cardia due to sympathetic predominance. In some cases of cardiospasm (achalasia) prostigmine and ergotamine can produce a beneficial effect.

CHAPTER 37

Digestion in the Stomach

THE STOMACH IS NOT an indispensable organ; it has been completely extirpated in man and animals, and although this operation causes certain disturbances in digestion, they are not incompatible with a normal healthy life. In man the most important function of the stomach is the transformation of food into a homogeneous semifluid mass, the chyme. The stomach also acts as a reservoir of food during the process of digestion, the chyme being passed into the duodenum in small quantities. Gastric juice, owing to its high acidity, has bactericidal activity.

FIG. 165. Diagram of method for registering gastric contractions.

GASTRIC MOTILITY

Methods of study. Many methods have been devised for the study of gastric motility: simple inspection, photography or cinematography of the movements of the stomach after laparotomy or through a window in the abdominal wall, the registration of variations in the gastric pressure by means of a balloon placed in the stomach (Fig. 165), the registration of the electrical phenomena of the stomach wall, etc. The study of isolated, living strips of stomach muscle has also been fruitful. The use of x-rays after ingestion of a meal with a substance opaque to x-rays, such as barium, is undoubtedly the method that has given the greatest amount of information on the movements of the stomach in experimental animals and man.

The structure, shape, and position of the stomach. The stomach is a hollow viscus the walls of which are formed by three muscular layers, covered by the peritoneum on the outer surface and by the gastric mucosa, with the muscularis mucosae, on the inner surface. The external muscular layer is formed by longitudinal fibers, the middle layer by circular fibers, and the internal layer of oblique fibers,

which originate around the cardia, sweep down the smaller curvature, and end by joining up with the circular fibers. At the level of the pylorus the circular fibers are thicker and form the pyloric sphincter. The external and middle layers are more important than the internal one.

In man the stomach has the shape of a J, of a reversed L, or of a steer's horn (Fig. 166). The lowest point of the greater curvature is below a line joining the iliac crests in the majority of individuals in the standing position; in some cases the stomach goes well down into the pelvis. These cases are due not to ptosis or dropping of the stomach but to its lengthening, since the fundus remains in contact with the diaphragm.

FIG. 166. Different types of stomach filled with an opaque meal: *a*, stomach of the reversed-L type; *b*, steer-horn type of stomach; *c*, J type of stomach.

For descriptive purposes the stomach can be divided into two parts: the body and the pylorus, separated by the incisura angularis (Fig. 167). The part of the stomach above the cardia is called the fundus and is usually full of air. The pyloric part comprises the antrum or pyloric vestibule and the pyloric canal. This canal is surrounded by the pyloric sphincter and ends in the duodenal cap or bulb, which is the first part of the duodenum.

The tonus of the stomach. In the empty stomach the cavity is obliterated by the apposition of its walls except at the level of the fundus, which is distended by gas. The arrival of food in the stomach separates its walls, and as the viscus is distended the muscular layers relax, adapting the volume of the cavity to its contents, without any increase, or only a transient one, in the intragastric pressure. This postural tone, common to all hollow viscera, is maintained by a special adaptative mechanism (receptive relaxation). Swallowing causes relaxation of the gastric musculature.

Movements of the stomach. The activity of the fasting stomach passes through three main phases (Fig. 168): (*a*) active contractions, which last 30 to 40 sec. and take place at intervals varying from 10 sec. to 5 min.; (*b*) rhythmic changes in tonus; (*c*) relative quiescence. Usually after a period of activity, which lasts 30 to 60 min., there is another of quiescence, followed by a stage of rhythmic tonus.[1] The
FIG. 167. Diagram of the subdivisions of the human stomach.

[1] ANDERSON, W. F., *Lancet*, 1, 40, 1943.

active periods are usually accompanied by a sensation of hunger,[1] which may be painful.[2]

Almost immediately after the ingestion of food, a peristaltic wave commences in the middle of the body of the stomach, increases in strength at the level of the incisura, and ends in the neighborhood of the pylorus. The upper part of the body of the stomach and the fundus seldom show peristaltic activity.

FIG. 168. Principal types of activity of the fasting stomach: *a*, active contractions; *b*, variations in tonus; *c*, relative quiescence. (*Anderson, W. F., Lancet, vol. 1, p. 40, 1943.*)

Peristaltic waves follow each other rhythmically every 15 to 20 sec.; they take from 15 to 30 sec. to travel down the stomach, and they can be of several types. Sometimes on arriving at the antrum they provoke a systolic contraction of the circular fibers of the whole antrum. At other times peristaltic waves go all the way to the pyloric sphincter. Some of the waves die out soon after they have started. When the pylorus is closed the food flows back into the stomach; the repetition of this maneuver kneads the food and mixes it with the gastric juice.

These movements are kept up as long as there is food in the stomach. The body of the stomach functions as a reservoir; food can remain there for a long time without change. The antrum has a double function: it mixes the contents (the pyloric mill) and evacuates the stomach. The different foodstuffs are mixed with each other and with the digestive juices, being transformed into a semiliquid paste called the chyme. Periodically the pylorus opens and a portion of chyme is passed into the duodenum. Peristaltic waves are not indispensable for the evacuation of the stomach; if the intragastric pressure is greater than the duodenal pressure and the pylorus is open, the chyme flows into the duodenum.

Innervation of the stomach. Peristaltic movements of the stomach can be observed in the denervated stomach and in stomachs that have been extirpated and kept alive by perfusion. Therefore this type of contraction is not dependent on the impulses carried by the vagus and the sympathetic nerves. The walls of the stomach, like those of the rest of the alimentary canal, contain two nerve plexuses, those of Auerbach and Meissner, which undoubtedly play a part in the coordination of the tonic and rhythmic contractions of the different parts of the viscus. According to Cannon, the peristaltic contractions of the antrum are myogenous, as they persist after Auerbach's plexus has been destroyed.

Stimulation of the vagus or of the sympathetic produces variable results on the stomach and on the pyloric sphincter. The effect of the vagus on the musculature of the wall and the pyloric sphincter is predominantly excitatory, and that of the sympathetic is predominantly inhibitory. Nevertheless the results of stimulation depend on the condition of the stomach muscle at the

[1] CANNON, W. B., and A. WASHBURN, *Am. J. Physiol.*, **29**, 441, 1912.

[2] CARLSON, A. G., "The Control of Hunger in Health and Disease," University of Chicago Press, Chicago, 1916.

moment. Hence, if there is a high tonus or the muscle is actively contracting, stimulation of either nerve produces relaxation. On the other hand if the muscle is relaxed and quiescent, stimulation of either nerve increases tone and awakens peristalsis. The immediate effect of double vagotomy is the loss of tone and motility, but soon both are recovered. Sympathectomy does not produce any notable change, although sometimes there is an immediate but transient increase in motility.

Acetylcholine is released on stimulation of the vagus, and sympathin on stimulation of the sympathetic. These substances are chemical mediators of stimulation that act directly on the effectors. Acetylcholine and other choline esters increase the tone and motility of the stomach. The same effect is obtained with eserine and prostigmine, drugs that inhibit cholinesterase. Atropine and adrenaline inhibit the movements of the stomach.[1]

The pyloric sphincter. The pyloric sphincter is formed by the distal segment of the circular fibers of the pyloric part of the stomach. Between the sphincter and the muscular layer of the duodenum there is a barrier of connective tissue, which is bridged by only a few muscle fibers. The pyloric muscle is autonomous and contracts after complete denervation. Nevertheless both the vagus and the sympathetic have a certain action on the sphincter, the former mainly excitatory, the latter mainly inhibitory. The pylorus responds to impulses originated in the hypothalamus; for this reason, in nervous and emotional states signs of pyloric spasm are sometimes observed.

The pylorus (Greek πυλη, door, and οὐρος, keeper) has been considered the sole regulator of gastric evacuation. This opinion can no longer be maintained, as after extirpation of the pylorus or a gastroenterostomy, the emptying of the stomach takes place with no significant alteration. Moreover, during gastric evacuation the pylorus is open most of the time.[2]

When the stomach is empty, the pylorus remains open with an occasional rhythmic contraction. After the ingestion of liquid or semiliquid substances gastric evacuation begins immediately and is soon ended. Solid food remains in the stomach until it is converted by the gastric juice and the kneading action of the antrum into a semiliquid paste. Only then does the stomach begin to empty, a process which takes 3 to 4½ hr. according to the nature of the meal. Carbohydrate is evacuated more rapidly than meat, and fat remains even longer in the stomach (Fig. 169).

The mechanism of gastric evacuation. There is some discussion as to the mechanism of gastric evacuation. At first it was believed that the peristaltic waves forced the stomach contents into the duodenum, if the pylorus was open. There is seldom a contraction sufficiently strong to separate the antrum from the rest of the stomach; the intragastric pressure is therefore not often modified to any considerable degree by peristaltic contractions. More recent work has shown that the most important factor in the evacuation of the stomach is the difference between the intragastric and the intraduodenal pressures; the contents of the stomach are evacuated when the gastric pressure is higher than the duodenal pressure and the pylorus is open. The gastric pressure rises above the duodenal pressure (*a*) when there is increase of gastric tonus or contraction of the whole stomach; (*b*) when there is relaxation of the duodenum; (*c*) when both these conditions occur simultaneously. Any agent that diminishes gastric tone or motility, or increases the duodenal tone, will diminish, annul, or reverse the gradient of pressure. It will therefore retard gastric evacuation or even cause regurgitation of the duodenal contents into the stomach.

Distention of the stomach by the ingestion of food stimulates its motility; intragastric pressure increases, and the evacuation of the stomach is facilitated. The evacuation time of the stomach is not significantly modified by the condition of the pylorus.[1] The tonus and peristaltic movements of the stomach are strongly influenced by duodenal factors. Distention or mechanical irritation of the duodenum, hypertonic or hypotonic solutions, and HCl in the duodenum inhibit gastric motility and lengthen the evacuation of the stomach. Fats[2] and carbohydrates[3] have the same effect; they act reflexly and by

means of a humoral mechanism (enterogastrone). Products of protein digestion (proteoses, peptones, and amino acids) act reflexly through the vagus nerves.[1]

Quigley[2] describes gastric evacuation in the following words: "A small portion of the gastric contents enters the intestine. If the sample proves satisfactory, the remainder leaves the stomach rapidly; unsuitable material initiates reactions from the duodenum which temporarily retard further gastric evacuation."

Fig. 169. Time taken to evacuate different foods from the stomach. Except where the amount is specified, the diagram refers to 100-gm. portions. (*Hawk and Bergeim, "Practical Physiological Chemistry," 11th ed., The Blakiston Company, Philadelphia, 1937.*)

The emptying time of the stomach. From what has been said it can be deduced that the principal factors that have an influence on the emptying time of the stomach are (*a*) the intragastric pressure, determined by the tonus and the rhythmic contractions of the stomach muscles; (*b*) the pressure in the duodenal cap, governed by factors similar to those acting on the stomach; (*c*) the state of contraction or relaxation of the pyloric sphincter. The three factors are mainly dependent on stimuli arising in the duodenum.

Water and certain liquid or semiliquid substances pass almost immediately into the duodenum, even when the stomach does not contract; the difference in pressure normally existing between the stomach and the duodenum is sufficient to cause this. However, if the fluid is strongly acid or alkaline, or if it is hypertonic, it takes longer to leave the stomach, because as soon as some enters the duodenal cap it stimulates the closure of the pylorus; for evacuation to continue, the fluid now in the duodenum must be neutralized or diluted.

Table 31. Composition of Food and Gastric Evacuation Time

Composition	*Evacuation Time*
Normal: 2 scrambled eggs with butter, bread, coffee, and milk; total fat, 50 gm.	6 hr.
Fat-poor: 2 boiled eggs, bread, coffee	4 hr., 45 min.
Fat-rich: 2 scrambled eggs with butter, bread, coffee, milk, and 100 gm. butter	After 6 hr. only 60 per cent had been evacuated

Source: Wolf, S., and H. G. Wolff, "Human Gastric Function," Oxford, New York, 1943.

The time of evacuation of solid foods depends on the speed with which they are transformed

[1] Thomas, J. E., and J. O. Crider, *Am. J. Physiol.*, **126**, 28, 1939.

[2] Quigley, J. P., *Arch. Surg.*, **44**, 414, 1942.

into a semiliquid mass, which does not stimulate the duodenum as solids do. Carbohydrates are evacuated more rapidly than proteins; fats remain a longer time in the stomach (Table 31).

Factors which modify gastric tonus and motility condition the evacuation time of the stomach. This time is shorter in hypertonic (steer-horn-shaped) than in hypotonic (J-shaped) stomachs.[1] Rapidity of evacuation seems to be directly related to the volume of the gastric contents; distention of the stomach reflexly increases its tonus and motility.[2]

Enterogastrone (see Chap. 35), secreted by the duodenum when stimulated by fats, fatty acids, sugars, etc., inhibits gastric secretion and motility. Urogastrone has the same effect. Insulin increases gastric motility. Hypoglycemia produced by this hormone stimulates hypothalamic centers, and motor impulses are conducted by the vagus nerves to the stomach. Section of both vagi suppresses the effect of insulin on gastric motility.

Alcohol, caffeine, and choline increase gastric motility, and tobacco, atropine, and banthine[3] (see "Effects of certain drugs on gastric secretion," page 359) depress it.

VOMITING

Vomiting is a complicated act which produces the ejection of the gastric contents through the mouth. Usually vomiting is preceded by a sensation of nausea, which coincides, according to Barclay, with a decrease in the tonus of the stomach; there is also excess salivation and the respiratory rhythm is modified. Retching follows these preliminary phenomena. This is due to uncoordinated movements of the respiratory muscles; the diaphragm and the expiratory muscles contract simultaneously.

Vomiting begins with a deep inspiration, the glottis is closed, and the soft palate is raised so as to close the nasopharynx. The diaphragm and the abdominal muscles contract strongly. The cardia and the esophagus relax; the body of the stomach also relaxes. Frequently there is a strong peristaltic wave, which sometimes divides the stomach into two cavities at the level of the incisura. All these movements are combined so as to expel the stomach contents. The small amount of food that remains in the esophagus after vomiting has ceased is evacuated by the increase in thoracic pressure, which results from the relaxation of the diaphragm together with the contraction of the expiratory muscles, and by antiperistaltic movements in the esophagus.

At one time it was thought antiperistaltic contractions of the stomach were of great importance in the mechanism of vomiting. However, antiperistalsis is not observed; on the contrary, the wave of contraction that starts in the incisura frequently travels down to the pylorus as in the normal movements of the stomach. Magendie demonstrated, over a century ago, that the stomach musculature does not play an essential part in vomiting. He replaced the stomach of a dog by a hog's bladder and then provoked vomiting, which ejected the contents of the bladder through the mouth.

The increase in intragastric pressure, produced by the contractions of the diaphragm and the abdominal muscles, would be ineffectual if the cardia and the esophagus did not relax at the same time. Defecation and coughing are also accompanied by a great increase in intra-abdominal and therefore intragastric pressure, but there is no vomiting because the cardia does not relax. Some animals, such as the horse, the rabbit, and, generally speaking, the herbivora, do not vomit. In some instances, *e.g.*, in the horse, this seems to be due to the lack of relaxation of the cardia; ineffectual vomiting movements occur, which are occasionally so strong that the stomach bursts. In other animals there is no coordinating center for vomiting movements.

The nervous mechanism of vomiting.[1] According to Hatcher, vomiting is always a reflex movement, which can start in many different parts of the body. Afferent pathways carry the impulses to the center in the medulla, whence coordinated impulses are sent out to the muscles.

The following stimuli can provoke vomiting:

1. Mechanical stimulation of the isthmus of the fauces. The afferent path is the trigeminal or the glossopharyngeal.
2. Irritation of the stomach by food or drugs: tartar emetic, mustard, ipecac, mercuric

[1] Hatcher, R. A., *Physiol. Rev.*, **4**, 479, 1924.

chloride, zinc sulfate, etc. The afferent path is constituted by fibers included in the vagus, the sympathetic, or both nerves, according to which agent is present.

3. Distention, compression, or irritation of the abdominal viscera: intestine, appendix, bile ducts, uterus, kidney, etc.
4. Dilatation of the heart and other stimuli, such as digitalis and pilocarpine, which act on this organ. The afferent impulses travel along the cardiac nerves.

These afferent impulses are integrated in the "vomiting center," a localized area in the reticular formation of the medulla,[1] the destruction of which makes vomiting impossible. Borison and Wang have also located an area on the ala cinerea of the fourth ventricle which is sensitive to apomorphine and digitalis glucosides.[2] These substances do not act directly on the vomiting center but on chemoreceptors in the fourth ventricle, and perhaps on peripheral chemoreceptors. Efferent impulses of the reflex travel (*a*) along the vagus to the stomach; (*b*) along the phrenic nerves to the diaphragm; (*c*) along the spinal nerves to the abdominal muscles. There are also inhibitory impulses which go from the center to the cardia and esophagus.

The excitability of the center varies in different individuals, and in the same individual in different circumstances. Hatcher maintains that the center is constantly receiving impulses from all parts of the body, which do not result in vomiting because they cause only subliminal excitation. When the excitability of the center increases—*i.e.*, when the threshold is lowered, as in certain psychic states, in fatigue, and by some drugs (apomorphine, emetine, etc.)—the usual afferent impulses are enough to cause vomiting. On the contrary if the excitability of the center is lowered, a previously efficacious stimulus no longer provokes vomiting. This decrease in excitability is obtained by increasing the activity of neighboring centers and by giving certain drugs (barbiturates, etc.). Nausea and vomiting form part of the syndrome of vertigo and seasickness.

GASTRIC SECRETION

The gastric glands. The gastric mucosa, from the cardia to the pylorus, has many glands. These are of three different types. Around the cardia there are composite tubular glands, the cardiac glands. In the pyloric region there are short glands with a long and sinuous excretory duct, the pyloric glands. In the mucosa of the body or fundus of the stomach, the peptic or principal glands are found; they have straight excretory ducts which end in the fovea of the mucosa. The pyloric glands resemble the Brünner glands of the duodenum; they secrete an alkaline juice rich in mucus. There are three types of cells in the principal glands: (*a*) the chief, zymogenic, or peptic cells, which are cylindrical in shape, have poorly marked contours, and are mostly found in the body of the gland; (*b*) the parietal, border, or oxyntic cells, which are of varying shape, have well-marked contours, are placed between the basal membrane and the chief cells, and are more numerous in the neck of the gland; (*c*) mucous cells, which are found in the neck of the gland. The chief cells secrete pepsinogen, the constituent substance of the cytoplasmic granules; these granules decrease in amount when the cells secrete. The parietal or border cells secrete hydrochloric acid and for this reason are also known as oxyntic cells.

Gastric Juice

Gastric juice is a mixed secretion from the tubular glands of the stomach. Gastric juice must be distinguished from the gastric contents, which is the small amount (30 to 50 cc.) of fluid made up of gastric juice, mucus, saliva, and duodenal content that is found in the fasting stomach or that can be removed from the stomach after a meal.

Methods of collecting gastric juice. In man the contents of the stomach can be obtained by a catheter. The contents are removed for analysis 1 to 2 hr. or every 15 min. after a test meal.

Analysis of human gastric juice. A procedure usually followed is to (*a*) introduce a special catheter into the stomach; (*b*) draw out the contents of the stomach; (*c*) give a test meal (one commonly used is that of Ewald-Boas, which consists of 250 cc. of weak tea, 35 gm. of toasted bread, and 10 gm. of sugar); (*d*) withdraw from 5 to 6 cc. of the contents every 15 min. until the stomach is empty.

Total acidity, free acidity, pH, peptic activity, etc., can be determined in the samples. Total and free acidity are measured with a 0.1 *N* solution of Na(OH) and appropriate indicators. Free acidity is determined by the use of indicators that change color at pH 3 to 4.6 (bromophenol blue, etc.); total acidity by the use of indicators that change color at pH 8.3 to 10 (phenolphthalein, etc.). Acidity is measured in terms of the amount of 0.1 *N* Na(OH) necessary to neutralize 100 cc. of gastric juice, or the amount of HCl that corresponds to 100 cc. of gastric juice, *i.e.*, the percentage of hydrochloric acid (1 cc. of 0.1 *N* HCl contains 0.00365 gm. of HCl) (Fig. 170).

FIG. 170. Typical curves of gastric acidity following a test meal. Solid line, total acidity; broken line, free hydrochloric acid. Scale in minutes.

Pure gastric juice can be obtained by first washing out the stomach and then injecting subcutaneously 0.01 mg. of histamine per kilogram of body weight. This procedure normally produces about 200 cc. of gastric juice in 1 hr. The secretion so obtained is not normal gastric juice because histamine stimulates mainly the secretion of hydrochloric acid and to a lesser degree the secretion of mucus and pepsin.

Cases of accidental or surgical fistulas of the stomach have been of great use in the study of gastric secretion in man.

Between the years 1825 and 1833 William Beaumont[1] made a series of observations and experiments on a Canadian hunter, Alexis St. Martin, who had a gastric fistula as a consequence of having been accidentally shot in the abdomen three years before. St. Martin was nineteen years old at the time of the accident and he lived with his fistula to the age of seventy-eight. In 1876 gastrostomy in a case of cancer of the esophagus was performed for the first time; Richet studied this patient and confirmed many of Beaumont's observations. Later many similar studies on patients with gastric fistula were published. Those of Carlson[2] and Wolf and Wolff[3] are particularly notable for the wealth of detail and care with which they have been made.

Pavlov[4] developed the technique of obtaining

[1] BEAUMONT, W., "Experiments and Observations on the Gastric Juice and the Physiology of Digestion," Plattsburg, 1833.

gastric juice in the dog. To avoid contamination of the gastric secretion with saliva and the products of digestion, Pavlov combined a gastric fistula with one in the esophagus (Fig. 171) and improved Heidenhain's gastric pouch. Pavlov's operation consists in completely separating a part of the stomach by a layer of the mucosa, leaving a bridge of the muscular layer and the peritoneum so that the vascular and nervous connections remain intact (Fig. 173).

FIG. 171. A dog with fistulas in the esophagus and stomach, held in Pavlov's holder.

The properties of gastric juice. The amount of gastric juice secreted in 24 hr. varies in different circumstances. The fasting stomach of man secretes 8 to 15 cc. of gastric juice per hour. The composition, acidity, and digestive potency vary considerably, because gastric juice is a mixture of the secretions of several types of gland which respond differently to different stimuli. The isotonic solution of HCl secreted by the parietal cells is diluted and in part neutralized by the secretions of other cells in the gastric mucosa. Gastric juice is a clear, colorless fluid, without smell and strongly acid (pH 0.9 to 1.5). The specific gravity is 1.006 to 1.009 and the freezing point −0.55 to −0.62°C. The principal components are hydrochloric acid, mucus, and enzymes; the enzymes are pepsin, cathepsin, rennin, and a very small amount of lipase.

The activity of gastric juice. The *mucus* in gastric juice protects the mucosa from irritating substances, neutralizes the acid in the gastric content, and forms a precipitate when the acid is in high concentration.

The digestive activity of gastric juice is due in great part to *pepsin.* The principal cells of the glands in the fundus secrete *pepsinogen,* which is converted into pepsin by the HCl secreted by the parietal cells of these same glands. Pepsin is a proteinase, *i.e.*, an enzyme that acts on proteins of high molecular weight; it hydrolyzes the peptide bonds and transforms most proteins into proteoses and peptones. It has a maximum activity at pH 1.5 to 2. This high acidity in the stomach is due to the secretion of hydrochloric acid. Nevertheless in the first 2 hr. after a meal the pH of the gastric contents is between 5 and 6, because of the buffer action of the proteins in the food. Pepsin is inactive at this pH. In other words, pure gastric juice has active pepsin but no substrate on which this enzyme can act; on the other hand the gastric content after a meal has abundant substrate, but pepsin is inactive. A second proteolytic enzyme has been discovered in gastric juice, which has the properties of a *cathepsin.* This enzyme acts on proteins of high molecular weight, just as pepsin does, but its optimum pH is between 3 and 5. According to Buchs[1] cathepsin and pepsin are two enzymes. At the beginning of digestion, while the gastric content has a pH of 3 to 5, cathepsin only is active; later, in the third hour after the ingestion of food, the pH falls to a level at which pepsin becomes active. In brief, cathepsin commences proteolysis in the stomach and pepsin ends it.

Hydrochloric acid not only produces an adequate medium for the activity of pepsin but also has an important digestive effect; it dissolves and disintegrates nucleoproteins, dissolves collagen, precipitates the caseinogen of milk, hydrolyzes sucrose into glucose and fructose, etc.

[1] BUCHS, S., "Die Biologie des Magenkathepsins," ed. Karger, Basel, New York, 1947.

An antiseptic function has also been attributed to HCl; the acidity of gastric juice prevents the development of bacteria of putrefaction and lactic fermentation, and of several pathogenic microbes. Hydrochloric acid also plays a part in the formation of secretin.

Rennin (*Labferment*, *présure*, *cuajo*) is also a protease found in gastric juice. It is formed from a zymogen by the action of acid. This enzyme is found in large amounts in the fourth stomach of calves; it activates hydrolysis of the caseinogen (casein) of milk and transforms it into casein (paracasein). Calcium is necessary for this process, which results in the coagulation (curdling) of milk due to the precipitation of calcium caseinate. The optimum pH for rennin activity is 5.35. Tauber and Kleiner's[1] work has shown that rennin and pepsin are two different enzymes, and thus a long-standing discussion as to the possible identity of these enzymes has come to an end. Nevertheless pepsin and other proteolytic enzymes can coagulate milk, and the existence of rennin in human gastric juice and in the stomach of other mammals has not been definitely proved.

The principal function of gastric juice in the digestion of fats is to dissolve the protein membranes of adipose cells. It also contains a weak *lipase* which disintegrates alimentary fats already emulsified (egg yolk, etc.). Its effects are produced mostly at the beginning of gastric digestion, when the acidity is not too high. The optimum pH is around 6, varying somewhat in different species.

Gastric juice contains an *intrinsic factor*, which acts on an *extrinsic factor* found in several foodstuffs and forms the *hematinic principle* or *antianemic factor*, which is necessary for the normal development of red blood cells. The intrinsic factor is neither hydrochloric acid nor any of the enzymes already mentioned (see Chap. 5).

The formation of hydrochloric acid. The parietal cells secrete hydrochloric acid at a constant concentration. Their product of secretion seems to be an isotonic solution of HCl, which contains 166 mEq./liter Cl^-, $159H^+$, and $7K^+$.[2] The parietal cells can concentrate H^+ to a million times the value of its concentration in the blood. This extraordinary process

[1] TAUBER, H., and I. S. KLEINER, *Ztschr. f. physiol. Chem.*, 220, 205, 1933; KLEINER, I. S., and H. TAUBER, *J. Biol. Chem.*, **106**, 501, 1934.

has been the object of much study. One of the theories put forward to explain it, which has wide acceptance, is that carbonic acid acts on intracellular disodium phosphate and forms monosodium phosphate, which with sodium chloride gives hydrochloric acid and disodium phosphate.

$$Na_2PO_4 + H_2CO_3 \rightarrow NaHPO_4 + NaHCO_3$$
$$NaHPO_4 + NaCl \rightarrow Na_2PO_4 + HCl$$
Carbonic acid is formed from the CO_2 in the blood by the action of carbonic anhydrase.

The following facts support this theory: (*a*) there are large amounts of carbonic anhydrase in the gastric mucosa; (*b*) an increase in the partial pressure of CO_2 in the blood plasma causes an increase in HCl concentration in the gastric juice;[1] (*c*) the parietal cells contain an exceptionally large quantity of phosphates.

The following alternative hypotheses as to the genesis of HCl have been put forward: (*a*) intracellular hydrolysis of NaCl;[2] (*b*) intracanalicular secretion of KCl, with subsequent reabsorption of K, which is replaced by hydrogen ions produced by cellular metabolism;[3] (*c*) secretion of an organic acid, probably pyruvic acid, into the canaliculi, with reabsorption of the acid radicals and replacement by Cl ions;[4] (*d*) release of H^+ by the oxyntic cells using energy obtained from the metabolization of glucose.[5] Recent work has shown that HCl is not formed when there is lack of thiamine or nicotinic acid, vitamins which play a part in the production and destruction of pyruvic acid.

THE MECHANISM OF GASTRIC SECRETION[6]

The normal resting stomach secretes continuously small amounts of gastric juice (basal secretion of the gastric mucosa).[7] The ingestion of food increases the flow of gastric juice. The ac-

tivity of the different types of cell which make up the gastric glands is conditioned by nervous, hormonal, and chemical factors, which act to stimulate or inhibit each group of cells. The properties of the juice secreted vary with the stimulus and the response that it provokes. For example, appetite secretion and the secretion produced by sham feeding or a real meal are rich in pepsin. Injection of acetylcholine, pilocarpine, and insulin also provokes the secretion of a gastric juice rich in pepsin.

Two periods must be considered in studying gastric secretion: the resting period and the digestive period.

SECRETION DURING REST

The amount of gastric juice secreted between the digestive periods is usually small, and the concentration of pepsin and HCl is variable; frequently no HCl is secreted. Pavlov believed that a psychic stimulus was necessary for the secretion of HCl in this condition, but more recently it has been found that such a stimulus is not indispensable, at least in man (Babkin). The causes of this continuous secretion of gastric juice in the intervals between the digestive periods are not yet known, but probably there are psychic, nervous, and chemical stimuli (Babkin).

SECRETION DURING DIGESTION

There are three phases in the secretion of gastric juice provoked by a meal: the *cephalic*, the *gastric*, and the *intestinal*, so called because of the site of stimulation.

The cephalic phase. The stimuli responsible for this phase act on receptors situated in the head. The contribution of Pavlov and his pupils to the knowledge of this phase has been so important it could well be called the "Pavlov phase."

In a hungry dog with a gastric fistula (Fig. 171) it is possible to demonstrate that the mere sight of food provokes a flow of gastric juice within a few minutes. The smell of food or any other stimulus that has been naturally or artificially associated with the ingestion of food produces the same effect. This "psychic secretion" or "appetite secretion"[1] has also been demonstrated in man, being similar to the secretion of saliva provoked by these same stimuli. Gastric secretion is due in these cases to a "conditioned" reflex. Gastric secretion can also be produced by suggestion in a hypnotized subject. On the other hand, an intense emotional state inhibits gastric secretion previously provoked by an adequate stimulus.

[1] The term "appetite secretion" should be preferred; the term "psychic secretion" is more appropriate for the flow caused by mental images, hypnosis, etc.

When food is given to a dog with a fistula in the esophagus and another in the stomach (sham feeding),[1] gastric juice commences to flow from the gastric fistula in 10 to 15 min. Food and substances with pleasant taste stimulate the taste buds and reflexly through the vagus provoke gastric secretion. Chewing tasteless substances, such as rubber or sponge, does not have this effect.

Psychic secretion and the secretions of appetite and of sham feeding are of reflex origin. The first two are conditioned reflexes; the cerebral cortex plays an important part in their production. Decerebrate dogs do not secrete gastric juice on being shown food or made to smell it, but they respond to sham feeding.[2] In all these cases the vagus is the efferent path of the reflexes. Section of both vagi or the injection of atropine suppresses psychic or appetite secretion and that following sham feeding.

Electrical stimulation of the vagus provokes secretion of gastric juice as a result of the activity of the different types of glandular cells in the stomach. Uvnäs[3] has shown that intravenous injection of an extract of pyloric mucosa increases the secretory effect of excitation of the vagus, and that this effect diminishes if the pyloric region of the stomach is tied off or removed. Stimulation of the vagus has, therefore, a twofold effect: it stimulates the peptic glands directly, and it stimulates secretion of gastrin by the mucosa of the pyloric region, thus stimulating the peptic glands indirectly through a hormonal mechanism. Hormonal and nervous mechanisms thus act synergically.

The gastric phase. The stimuli that provoke gastric secretion during this phase act on the stomach.

Food is given to a dog with a Pavlov pouch and with both vagi cut so as to eliminate the cephalic phase; 20 to 45 min. later the miniature

[1] The food is chewed, tasted, and swallowed but is lost through the fistula in the esophagus.

[2] Zeljony, G. P., XI Internat. Physiol. Congr., Edinburgh, 1923.

[3] Uvnäs, B., *Acta physiol. Scandinav.*, **4**, Suppl. 13, 1942.

stomach begins to secrete. This is not a reflex secretion, since the portion of the stomach deprived of all its nervous connections[1] or transplanted to the region of the mammary gland[2] (Fig. 172) secretes gastric juice when food is introduced into the part of the stomach remaining *in situ*.
FIG. 172. Ivy's two-pouch dog with a duodenal fistula. *T.S.*, a portion of the stomach disconnected from the principal part and transplanted under the mammary gland; *I.S.P.*, stomach pouch disconnected from the rest of the digestive tract. (*Redrawn from Ivy, A. C., Surgery, vol. 10, p. 861, 1941.*)

The presence of food in the stomach stimulates the secretion of gastric juice. This fact can be demonstrated in a dog with a Pavlov pouch and a fistula in the principal part of the stomach (Fig. 173). When certain foods are introduced through the fistula directly into the stomach, taking care to avoid all psychic stimulation, gastric juice is secreted by the miniature stomach after an interval of 20 to 45 min.

Local mechanical stimulation. Pavlov observed that mechanical stimulation of the gastric mucosa by the introduction of pieces of sponge or sand, or by rubbing the mucosa with a glass rod or a rubber tube, did not provoke gastric secretion. On the other hand distention of the stomach was an efficient stimulus. A continuous flow of 50 cc. of water through the stomach does not provoke the secretion of gastric juice, but a larger volume (150 to 300 cc.) of water does stimulate secretion.

In the experiment described above, the miniature stomach cannot have been stimulated directly by a mechanical action on its mucosa, as it is empty; but since it still has nervous connections with the main part of the stomach, secretion might be due to a "local reflex." Ivy and Farrell transplanted part of the stomach into the mammary region (Fig. 172). This transplant had an outside opening, but was deprived of all nervous connections with the rest of the organism. Distention of the main part of the stomach did not provoke secretion in the transplanted mucosa; therefore the flow of gastric juice produced by distention of the stomach (see preceding paragraph) is due to local stimulation. The transplanted stomach, however, responds with a flow of acid gastric juice to: (*a*) the introduction of certain foods into the stomach *in situ*, and (*b*) distention of the pyloric region of the stomach *in situ*.[1] These experiments give definite proof that a hormonal factor, which stimulates the gastric mucosa, is released from the stomach during the gastric phase of secretion (see Chemical Stimulation).

FIG. 173. Pavlov's miniature stomach.

Chemical stimulation. Not all foods are capable of provoking gastric secretion when introduced into the stomach. Raw egg white, sugar, starch, and bread do not act as stimuli. On the other hand an abundant flow is produced by raw meat, meat extract, meat juice and broth, dilute alcohol, sodium bicarbonate, lactic acid, etc. The products of gastric digestion also act as stimuli; thus raw egg white, which is inactive, stimulates gastric secretion if it is previously digested with HCl and pepsin.

The pyloric portion of the stomach plays an important part in this phase of gastric secretion; the chemical stimuli of gastric secretion must act on this part of the stomach to produce their

effect. The experiments with transplanted stomachs referred to above exclude all possibility of a reflex mechanism; therefore a humoral agent must play a part.

The nature of this humoral agent is still under discussion. Several possibilities must be taken into account:

1. The stimulating substances could be absorbed and act directly through the blood stream. There are no proofs of this contention, and the positive results obtained by injection of meat and liver extracts might be due to the histamine they contain.
2. Histamine is considered by some to be the gastric hormone, liberated in the pyloric part of the stomach. If this were so it would act on the fundus after having been reabsorbed.[1]
3. The most probable mechanism by which many chemical substances stimulate gastric secretion when they come into contact with the pyloric mucosa is by provoking the formation of a special hormone, called "gastrin," which passes into the blood stream and provokes the secretion of the glands of the fundus. Edkins,[2] who first formulated this hypothesis, showed that intravenous injection of extracts of the pyloric mucosa have a stimulating effect on gastric secretion. Komarov[3] has prepared extracts of the pyloric mucosa free from histamine and choline. Extracts of the mucosa of the fundus and liver extracts do not produce gastric secretion. Pepsin and trypsin destroy the activity of gastrin; therefore it is of proteid nature.[4] The mechanism by which it is liberated during gastric digestion, absorbed, and conveyed by the blood stream to the fundic glands has not yet been demonstrated.

The intestinal phase. The stimuli that provoke gastric secretion during this phase act on the intestine. Chemical stimuli alone are active; distention of the gut and mechanical irritation of the intestinal mucosa do not produce gastric secretion.

Ivy and his collaborators have studied this phase in dogs with fistulas in the duodenum and

the stomach, or with the esophagus joined to the duodenum so that the stomach remains excluded, or with a duodenal fistula and a gastric transplant in the mammary gland (Fig. 172). In all these preparations it is possible to demonstrate that certain foods introduced into the duodenum or the jejunum stimulate gastric secretion. Water, meat, meat extract, meat juice or broth, peptones, soaps, and fatty acids are all active. Foods previously digested by pepsin and HCl are more active than undigested foods. The presence of bile seems to be an important factor in the activity of these substances.[1]

These observations show that the intestinal phase of gastric secretion is dependent exclusively on a humoral mechanism, either because a hormone (an intestinal gastrin) is formed in the duodenum and the jejunum and passes into the blood stream, or because the absorbed products of digestion act as stimuli on the fundic glands.

Inhibition of Gastric Secretion

Gastric secretion is inhibited in several conditions. Thus anoxia diminishes gastric secretion in man,[2] and adrenalectomy produces disturbances in the gastric secretion of the rat, of the type known as achylia.[3] The mechanism underlying these changes in the secretion of the stomach is not well known, but in other cases the cause of inhibition is better understood.

Nervous inhibition. Certain psychic states inhibit gastric secretion, as was mentioned before. Inhibitory fibers have been found in the vagi and the splanchnics. Distention of the gut inhibits gastric secretion, probably by a reflex mechanism.

Humoral inhibition.[4] By means of the same methods used to demonstrate the activity of certain substances that act on the stomach or the intestine and by a humoral mechanism stimulate gastric secretion, it is possible to show that other substances acting on the intestine have an inhibitory effect. Fats (olive oil, cream), concentrated solutions of sugar, or sodium bicarbonate inhibit gastric secretion, diminishing the flow and the pepsin and hydrochloric acid

content. Extracts of duodenal mucosa have been prepared which, when injected into an animal, inhibit gastric secretion.[1] The substance responsible for this effect has been called "enterogastrone." "Hormone" (Greek ὁρμαειν, to excite or awake) is the name given to those chemical messengers which, by means of the blood stream, increase the activity of an organ or a system; and "chalone" (Greek χαλαειν, to slacken) is that given to chemical messengers that have an inhibitory effect. Thus enterogastrone is a chalone, as it inhibits not only the secretion, but also the movements of the stomach. Extracts have been obtained that act only on the secretion but have no effect on the movements of the stomach, so it seems there are two different agents. In the urine of dogs and of man, a substance called "urogastrone"[2] has been found which has the same activity as enterogastrone and which probably is the latter after passing through the kidney. Recently Ivy and his collaborators have obtained a purified and concentrated enterogastrone which, when injected intramuscularly or intravenously, prevents the formation of experimental peptic ulcers in dogs and improves the patient's condition in cases of peptic ulcer in man.

Effects of Certain Drugs on Gastric Secretion

The action of certain drugs on gastric secretion is worthy of mention, as they are of use in the practice of medicine.

Subcutaneous injection of 1 mg. of atropine diminishes or suppresses in the dog the continuous secretion that takes place between the digestive periods and also the secretory response to a meal in all its phases—cephalic, gastric, and intestinal. The same dose diminishes, but does not suppress, the response to histamine. In a normal man injection of 1 to 2 mg. of atropine suppresses the continuous secretion and in some instances the secretory response to a meal. In some apparently normal subjects and in cases of duodenal ulcer, atropine has no effect; in these circumstances gastric secretion might be caused by the release of histamine, which is not inhibited by atropine.

Banthine (β-diethyl-aminoethylxanthene-9-carboxylate metabromide) is a salt of a quaternary ammonium which inhibits the effect of acetylcholine released by postganglionic parasympathetic fibers and blocks synaptic transmission in sympathetic ganglia. It has been used successfully in the treatment of gastrointestinal disturbances accompanied by hypersecretion and hypermotility.

Subcutaneous injection of 0.5 to 1 mg. of histamine increases considerably the flow of gastric juice with a high concentration of HCl and poor in pepsin and mucus. This effect is used as a test of gastric secretion in man, determining (*a*) the maximum acidity, *i.e.*, maximum concentration of acid, which in normal subjects is the equivalent of 102 cc. 0.1 *N* HCl solution per 100 cc. of gastric juice; (*b*) the volume of acid secreted per hour, which is normally 182 cc. 0.1 *N* HCl; (*c*) the flow of gastric juice per hour, which is normally 200 cc.

Caffeine, injected intramuscularly or given by mouth, stimulates gastric secretion in man and in the cat, but not in the dog.[1] This effect is not suppressed by vagotomy or the injection of atropine. Caffeine apparently acts not by liberating histamine but directly on the parietal cells.[2]

Sodium bicarbonate has a complex action. It neutralizes in part the acid contents of the stomach. If it is rapidly evacuated into the duodenum, as occurs when it is taken on an empty stomach, it inhibits gastric secretion by its effect on the duodenal mucosa. If it remains in the stomach, on the other hand, it acts on the pyloric mucosa and stimulates gastric secretion; finally it also has a stimulating effect once it has been absorbed from the intestine. Its use in therapy is justified only when an immediate neutralization of the gastric contents is desired.

Silica and aluminum gels are used in the treatment of peptic ulcers. They do not completely neutralize the gastric contents, but they do not stimulate gastric secretion, they are not absorbed, and they inactivate pepsin.

Insulin stimulates gastric secretion when it produces marked hypoglycemia; vagotomy suppresses this effect. The activity of pilocarpine is still under discussion. It is generally admitted that this drug stimulates the secretion of the gas-

[2] Roth, J. A., and A. C. Ivy, *Gastroenterology*, **5**, 129, 1945.

tric enzymes and mucus, but some workers also report the stimulation of hydrochloric acid secretion.

The Normal Course of Gastric Secretion

So far we have considered analytically the effects of the several stimuli that act on the flow of gastric juice and the experimental methods that serve to demonstrate the different phases of secretion, according to the place where these stimuli act. Now we can examine synthetically the normal course of gastric secretion.
Fig. 174. Diagram of Mann and Williamson's operation for producing experimental ulcers. (*Markowitz, "Textbook of Experimental Surgery," William Wood & Company, Baltimore, 1937.*)

When appetite is aroused (see above, The Cephalic Phase of Gastric Secretion) by the thought of a meal, or by the smell or sight of food, gastric secretion is stimulated by the conditioned-reflex mechanism. On taking food, within a few minutes an abundant flow is produced by way of the vagus nerve; the stimulus in this case is the taste of food. The amount of gastric juice secreted is directly proportional to the pleasure derived from the food. This is the most potent stimulus of gastric secretion, and its importance should be taken into account when considering alimentary hygiene. Food taken with relish because it provokes a pleasurable gustatory sensation will produce an abundant flow of gastric juice and its digestion will thus be furthered. Pavlov very aptly remarked that "appetite is the first and most important stimulus of the secretory nerves of the stomach; in the course of sham feeding, appetite causes the flow of great quantities of highly active gastric juice into the empty stomachs of our dogs. A good appetite at meal times is the source of a copious and active secretion; the absence of appetite means the absence also of gastric juice; the return of appetite assures an abundant secretion from the very beginning of the meal."

Psychic secretion and the reflex secretion of gustatory origin are responsible for the cephalic phase of gastric secretion. The arrival of food in the stomach in sufficient amount to distend it can act as a further stimulus to the gastric glands, but undoubtedly the humoral mechanism is the most important one in the gastric phase. Certain foods provoke the formation of gastrin by the mucosa of the pylorus; gastrin is absorbed and taken by the blood stream to the secretory cells of the stomach, which are thus stimulated into activity. This mechanism causes the persistence of secretion for a long time after the effects of the stimuli acting during the cephalic phase have ceased.

When food reaches the small intestine, gastric secretion is again stimulated by a humoral mechanism. It is yet doubtful whether this intestinal phase is due to the absorption of the products of digestion or to the formation in the duodenum and jejunum of a hormone that stimulates gastric secretion.

Inhibitory stimuli can act during any of the three phases. Certain psychic states, such as rage and fear, can stop or diminish gastric flow provoked by the stimuli mentioned above. Enterogastrone produced in the duodenum or jejunum also inhibits gastric secretion.

EXPERIMENTAL PEPTIC ULCERS

There are still many theories that endeavor to explain the causes of gastric and duodenal ulcers, but there is already a consensus as to which are the principal factors. Three main causes seem to have importance: (*a*) trauma to the mucosa, plus the corrosive action of hydrochloric acid and pepsin; (*b*) local circulatory disturbances of nervous or humoral origin; (*c*) chronic inflammation of the mucosa (gastritis).

The action of pepsin and hydrochloric acid seems

to be a factor common to all cases. Its importance is well demonstrated in Mann and Williamson's[1] procedure for the production of experimental ulcers: The duodenum is isolated by separating it from the pylorus and the jejunum. The proximal extremity of the duodenum is closed, and its distal end is joined to one of the end loops of the ileum. A gastrojejunostomy completes the operation (Fig. 174). By this means the bile and the pancreatic juice, which alkalinize the intestinal contents, are poured into the end of the small intestine, so that the acid chyme coming from the stomach is not neutralized. Chronic ulcers of the jejunum, situated close to the stomach opening, are observed in 95 per cent of animals so treated.

There are a great number of surgical techniques for the production of ulcers; they all combine trauma with the action of acid and pepsin.[2] Experimental ulcers can also be produced by prolonged treatment with atophan,[3] caffeine,[4] and histamine.

Vagotomy and peptic ulcer. Patients suffering from peptic ulcers secrete large quantities of gastric juice of high acidity, especially in the intervals between meals. Psychic factors acting through the vagi seem to play a major part in provoking this secretion. Double vagotomy at the level of the diaphragm has been performed in several of these cases, and a transitory decrease in the amount and acidity of gastric juice and in the movements of the stomach was observed.

CHAPTER 38

Intestinal Digestion

FOOD REMAINS IN the stomach for a longer or shorter time, according to the nature of the substances ingested, the way they have been prepared and masticated, the motility of the stomach, etc. While the food is in the stomach it is attacked by saliva (which continues to act as long as the acidity is not too great), by the gastric enzymes, and by hydrochloric acid. The gastric juice and the movements of the stomach convert the gastric contents into a semiliquid paste, definitely acid, which has been called the chyme. This chyme is passed through the pylorus into the duodenum at intervals and in small quantities. In the intestine it comes into contact with the secretions of the pancreas, the intestine, and the liver, which will be considered separately.

PANCREATIC SECRETION

The pancreas is a gland that has an external and an internal secretion. The islets of Langerhans secrete insulin, which passes directly into the blood, while the cells of the acini secrete a fluid known as the pancreatic juice.

Methods of collecting pancreatic juice. Pancreatic juice can be obtained from temporary or permanent experimental fistulas. In the first case, Wirsung's duct is opened and catheterized; in the second case, the part of the duodenum where Wirsung's duct ends is sewn onto the skin.

Dogs with a permanent pancreatic fistula, in which the greater part of the pancreatic juice is lost, show serious disturbances (loss of appetite, asthenia, dehydration) after a few days and eventually die. Life can be prolonged by giving the animals a milk diet and intravenous injections of sodium bicarbonate and other electrolytes (Ringer's fluid), so as to replace minerals lost through the fistula. The administration by mouth of the pancreatic juice that flows from the fistula is especially efficacious in prolonging life. A better method consists in making a duodenal fistula, through which the pancreatic duct can be catheterized; there is no loss of pancreatic juice with this technique.[1]

In man several cases of pancreatic fistula, following a surgical operation or abdominal wounds, have been studied. The results have confirmed experimental observations on dogs.

Pancreatic juice can be collected by passing a double catheter with one opening in the stomach and the other in the duodenum; contamination with gastric contents can thus be prevented.[2]

The properties and composition of pancreatic juice. Pure pancreatic juice, obtained from a temporary or permanent fistula, is a colorless fluid, somewhat viscous, transparent or slightly opalescent, and alkaline (pH 8.4 to 8.9) because of the presence of sodium bicarbonate. It has proteins that are coagulated by heat and precipitated by alcohol. Pancreatic juice obtained by stimulation of the vagus nerve or injection of pilocarpine is more viscous than that which results from the injection of secretin (see page 364); it also has a greater enzymatic activity, and is less alkaline.

THE ACTIVITY OF PANCREATIC JUICE

Action on proteins. Since 1834 it has been known that pancreatic extracts attack proteins. Claude Bernard,[3] in 1856, obtained pure pancreatic juice by catheterizing Wirsung's duct and saw it had no effect on proteins when it was pure.

[3] BERNARD, C., "Mémoires sur le pancréas," Paris, 1856.

Kühne[1] gave the name of "trypsin" to the substance responsible for the proteolytic effect of pancreatic juice. Shepovalnikov,[2] one of Pavlov's pupils, discovered the fact that intestinal juice activated the proteolytic effect of pancreatic juice; this was attributed by Pavlov to a substance that he called "enterokinase." Today it is known that pure pancreatic juice, collected by catheterization of Wirsung's duct, is inactive; it contains only a precursor or zymogen called "trypsinogen," which is transformed by a process of hydrolysis, activated by enterokinase (acting as an enzyme), into trypsin, a proteolytic enzyme. Trypsinogen and trypsin have been prepared in the crystalline state.[3]

Trypsin catalyzes hydrolysis of the peptide bonds of proteins and partially hydrolyzed proteins. Trypsin, in contrast to pepsin, attacks preferentially denatured proteins. For example, it has a weak action on natural egg albumen, seroglobulins, hemoglobin, collagen, etc., but digests these proteins easily if they have been previously modified by heat or other agents. Proteins are transformed by the action of trypsin into proteoses, peptones, polypeptides, and amino acids. Trypsin thus goes further than pepsin, which does not hydrolyze proteins as far as amino acids; nevertheless some polypeptides are not disintegrated even when the action of trypsin is considerably prolonged.

Trypsin develops its highest activity in an alkaline medium; the optimum pH varies between 8 and 9.7 for different substrates, but in a medium of such high alkalinity it is rapidly destroyed by autolysis. The duodenal contents are slightly acid (pH 4.5 to 5.1), because the acid chyme coming from the stomach mixing with the alkaline juices secreted by the pancreas, the duodenum, and the liver is only partially neutralized. Trypsinogen is rapidly transformed into trypsin by the enterokinase in the duodenum. The optimum pH for the enzymatic effect of enterokinase is 5.2 to 6. Trypsinogen is also transformed into trypsin by autocatalysis[4] at pH 7 to 9.

Action on milk. Another zymogen in the pancreatic juice is chymotrypsinogen, which is converted by trypsin into chymotrypsin in the duodenum. This enzyme is not trypsin, and enterokinase does not activate its zymogen. Both the enzyme and the zymogen have been obtained in crystalline form. This enzyme has a powerful curdling effect on milk.

[4] Kunitz and Northrop, *op. cit.*, p. 190.

Action on carbohydrates. Pancreatic juice contains an enzyme that acts like ptyalin, the amylase of saliva, hydrolyzing starch down to maltose. This amylase (amylopsin) has an optimum pH of 6.7 to 7.2. A maltase, which catalyzes the hydrolysis of maltose into glucose, is also found in pancreatic juice.

Action on fats. Claude Bernard demonstrated in a series of experiments, now classic, the emulsifying and hydrolytic action of pancreatic juice on fats.[1] A powerful esterase, known as the "pancreatic lipase" (steapsin), hydrolyzes neutral fats into fatty acids and glycerol. The hydrolysis of other esters is also catalyzed by this enzyme. Its optimum pH is about 8.0.

In an alkaline medium, bile has an important activating effect on pancreatic lipase. This effect is due exclusively to the bile salts. The absence of pancreatic juice causes serious disturbances in digestion, especially in the digestion and absorption of fats and fat-soluble vitamins.

Bicarbonate in pancreatic juice neutralizes the acidity of gastric juice and regulates the pH not only of the intestinal contents but also of the stomach when the contents of the duodenum are regurgitated into the stomach. Gastric function may thus be disturbed if there is no secretion of pancreatic juice.

The Secretion of Pancreatic Juice

Pancreatic juice is secreted intermittently in some animals; in others, *e.g.*, in the dog, rabbit, rat, guinea pig, and perhaps in man, it is secreted continuously. This continuous or "spontaneous" secretion may be caused by certain nervous and hormonal factors. The ingestion of food is followed after a short time by abundant flow of pancreatic juice.

Nervous mechanism. The pancreas is innervated by sympathetic and parasympathetic (vagus) fibers. Electric stimulation of the peripheral end of the cut vagus produces secretion of a small amount of pancreatic juice, rich in enzymes; there is an important ecbolic and a moderate hydrelatic effect. Secretin and vagal impulses act synergically; stimulation of the

[1] Bernard, *op. cit.*

vagus increases the response to secretin, and reciprocally the previous injection of secretin increases the response to stimulation of the vagus. Atropine suppresses the effects of vagal stimulation. Pilocarpine, acetyl-β-methylcholine, and other parasympathomimetic drugs have an ecbolic effect on the pancreas. Vagal stimulation can also interrupt or diminish the secretion provoked by other stimuli. This apparent secretory inhibition is probably due to the stimulation of fibers contained in the vagus nerve, which provokes contraction of the pancreatic ducts and prevents the flow of juice, which is thus retained within the ducts.

Stimulation of the sympathetic nerves also provokes the secretion of pancreatic juice rich in organic substances and enzymes. This effect is potentiated by eserine and inhibited by atropine; therefore it seems to be the result of the activity of cholinergic fibers in the sympathetic. Adrenaline and other sympathomimetic drugs have a predominantly inhibitory effect on pancreatic secretion, mainly due to vasoconstriction.

Humoral mechanism. Bayliss and Starling[1] showed that the introduction of acid into a loop of the jejunum, after severing all its nervous connections with the rest of the organism, provoked a flow of pancreatic juice in all respects the same as that observed in normal animals. It was already known that injection of acids into the blood stream did not stimulate pancreatic secretion.

The only barriers between the intestinal cavity and the blood stream are the intestinal mucosa and the capillary endothelium. Bayliss and Starling thought that acid must act on the intestinal epithelium, extracting a substance which, passing into the blood stream, stimulated the pancreatic cells. They prepared an extract of duodenal mucosa in 0.4 per cent HCl and, after neutralizing it, injected it intravenously; they obtained an intense secretory response. This now classic experiment demonstrated for the first time the existence in the organism of chemical substances that can stimulate distant organs into activity. These chemical messengers were called "hormones" by Bayliss and Starling.[2]

Conclusive evidence that the stimulus for pancreatic secretion is transmitted by the blood

[1] Bayliss, W. M., and E. H. Starling, *J. Physiol.*, 28, 325, 1902.

[2] See Chap. 51.

from the duodenum to the pancreas was given by experiments in which a duodeno-pancreas was grafted into the neck of a normal dog.[1] Injection of acid into the duodenum of the dog provoked a flow of juice from both the pancreas *in situ* and the grafted pancreas; therefore a chemical messenger goes in the blood from the duodenum to the pancreas and stimulates its secretory activity (Fig. 175).

The hormone in this mechanism was called "secretin" by Bayliss and Starling. It is found in the duodenal mucosa, and can be extracted not only by acids, but also by many other substances, such as water, soapy solutions, weak alkalis, etc. The amount of secretin that can be extracted from the intestinal mucosa diminishes as the distance from the pylorus increases.

Properties of secretin. Secretin has been purified, and crystals of its picrolonate have been obtained.[2] Apparently it is a polypeptide of low molecular weight (5,000), easily soluble, and diffusible through colloid membranes; it is destroyed by pepsin and trypsin. Its principal action is on the pancreas, but it also stimulates Brünner's glands of the duodenum, and the secretion of intestinal juice and bile. Secretion increases the flow of, and also the concentration of, bicarbonate in the pancreatic juice, but this juice is poor in enzymes, contrasting thus with the juice secreted in response to stimulation of the vagus nerve, or injection of choline derivates (mecholyl, etc.). Ergotamine and dehydroergotamine suppress the pancreatic response to secretin.[3]

Another hormone has been found in the duodenal mucosa; it is called "pancreozymin"[4] and it increases the enzymatic concentration of pancreatic juice, especially that of amylase. Pancreozymin can be separated from secretin by means of aniline, and it loses its activity after prolonged incubation with blood serum.[5]

Adaptation of the secretion of the principal enzymes to the diet has been demonstrated. Thus, after a time, a carbohydrate diet produces

[1] Delezenne, C., L. Hallion, and R. Gayet, *Ann. physiol. physicochim. biol.*, 3, 508, 1927; Houssay, B. A., and E. A. Molinelli, *Rev. Soc. argent. de biol.*, 3, 362, 1927.

[5] Greengard, H., M. I. Grossman, J. R. Woolley, and A. C. Ivy, *Science*, 62, 350, 1944.

pancreatic juice with a high concentration in amylase and a protein diet produces a juice rich in trypsin. On the other hand, fatty diets do not increase the content of lipase.[1] This may be the result of a process of adaptation, in the sense that ingestion of a certain kind of food stimulates production and secretion of the corresponding enzymes; or it may be that certain foodstuffs are necessary for the synthesis of enzymes, which does not take place if these substances are not found in the diet.[2] According to Babkin's observations in dogs and Lagerlöf's in men, the concentration of the three principal enzymes in pancreatic juice varies simultaneously, *e.g.*, when protease increases, lipase and amylase also increase.

Regulation of Pancreatic Secretion

There are a cephalic phase and an intestinal phase in the course of pancreatic secretion. There is no gastric phase; *i.e.*, introduction of food into, or distention of, the stomach does not provoke pancreatic secretion.[1]

The cephalic phase. The introduction of food into the mouth starts a reflex which produces the secretion of a small amount of pancreatic juice rich in enzymes. Atropine and double vagotomy suppress this reflex.
Fig. 175. Comparison of the effects produced on the secretions of the pancreas *in situ* and of the pancreas grafted into the neck, as shown by the number of drops of juice secreted per minute. Hydrochloric acid (30 cc., 0.5 per cent solution) was introduced into the small intestine *in situ* (*a*) and into a loop of small intestine grafted into the neck (*b*). Solid line: secretion of the grafted pancreas; broken line, secretion of the pancreas *in situ*. (*Gayet, R. "Titres et travaux scientifiques," Masson et Cie, Paris, 1933.*)

The intestinal phase. This is the most important stage of pancreatic secretion. All the principal constituents of the chyme (water, HCl, products of protein digestion, fats, fatty acids, digestive derivates of starch) stimulate pancreatic secretion when they are introduced into the duodenum. These substances produce the release of secretin, but the juice secreted in response to the introduction of foodstuffs into the duodenum has a higher concentration of enzymes than the juice obtained by injection of secretin or the introduction of HCl into the duodenum. The intestinal phase is, therefore, not due exclusively to secretin, but also to other factors, hormonal (pancreozymin) or nervous (true reflexes or local reflexes). Thus,

a grafted pancreas responds to the introduction of foodstuffs into the intestine with an increase in concentration of enzymes secreted in the juice, *i.e.*, a response corresponding to the release of pancreozymin.[1]

The formation of sodium bicarbonate. Probably enzymes are secreted by the cells of the acini, and the cells of the intralobular ducts secrete water and bicarbonate. The pancreas of an animal intoxicated with alloxan secretes enzymes normally, but the amount of fluid diminishes. This drug damages intralobular duct cells but does not affect the cells of the acini.[2] The pancreatic acini have the appearance of inverted gastric tubular glands. This fact, together with the results of alloxan intoxication, has led Thomas[3] to formulate the hypothesis that intralobular duct cells, and perhaps centroacinar cells, form bicarbonate by a mechanism similar to that by which HCl is formed in the glands of the stomach.

INTESTINAL SECRETION

The secretion of the glands of the mucosa of the small intestine is called intestinal juice. The crypts or glands of Lieberkühn secrete the intestinal juice; Brünner's glands, found exclusively in the first part of the duodenum, secrete an alkaline juice which is rich in mucus and which contains enterokinase, amylase, and traces of esterase.[1]

Methods of collecting intestinal juice. In the experimental animal the best way of obtaining intestinal juice and of studying its secretion is to make a permanent intestinal fistula. The Thiry and Thiry-Vella fistulas consist in the separation of a loop of intestine, with undisturbed innervation and circulation, and the connection of one or both ends of the loop to the skin (Fig. 176*a* and *b*). Pure intestinal juice can thus be obtained. To collect the intestinal contents metallic cannulas are placed at different levels in the gut (Pavlov). Mann and Bollman have substituted for the cannulas a strip of intestine (Fig. 176*c*).

In man accidental and surgical intestinal fistulas have given the opportunity of studying intestinal digestion. The intestinal juice has also been collected by introducing a rubber catheter into the gut through the mouth and stomach.

The properties and composition of enteric juice. Intestinal juice is usually a cloudy fluid, due to the presence of leukocytes, epithelial cells, and mucus. Sodium bicarbonate makes it more or less alkaline (pH 7 to 8.6). Apart from enterokinase, which transforms trypsinogen into trypsin, it contains several enzymes. The enzymes are found preformed in the mucosa, the extracts of which are more potent than enteric juice. Certain authors[2] maintain that only amylase and

enterokinase are truly secreted by the cells of the intestinal mucosa. They hold that other enzymes (peptidase, invertase, lipase, etc.) found in the lumen of the gut are not secreted but form part of the cells shed by the mucosa. Others[1] state that the four main enzymes of enteric juice are secreted simultaneously.

The amount and composition of enteric juice differ according to the level of the gut at which it has been collected and the nature of the stimulus used. As the distance to the pylorus increases, the amount of juice secreted and its enzymatic activity diminish.

The first part of the duodenum, where the Brünner glands are found, secretes an alkaline juice with abundant mucus. This secretion is stimulated by the local action of acids or foodstuffs, which release a hormone, *duocrinin*,[2] different from secretin.

The Activity of Enteric Juice

Action on peptides. Cohnheim gave the name of "erepsin" to the enzyme in the intestinal mucosa that acts on peptides. This is really an enzyme complex (aminopolypeptidase, dipeptidase, carboxypolypeptidase, polypeptidase)[3] which attacks the products of partial disintegration of proteins and transforms them into amino acids. Enteric juice does not act on native proteins, nor on proteoses and peptones.

Intestinal juice also contains *nucleinases*, which disintegrate nucleic acids into nucleotides, *nucleotidases*, which transform these nucleotides into phosphoric acid and nucleosides, and *nucleosidases*, which split nucleosides into pentose and purine bases. *Arginase* and *phosphatase* are found in the intestinal mucosa.

Action on fats. The intestinal juice has a weak *lipase*, which nevertheless can hydrolyze a good part of the fats in the food when there is no pancreatic juice.

Action on carbohydrates. The enteric juice completes the disintegration of carbohydrates which commences in the mouth and which is continued in the stomach by the saliva swallowed with the food and in the duodenum by the pancreatic amylase. The enzymes in saliva and pancreatic juice give disaccharides as final products; the enteric juice completes hydrolysis down to monosaccharides, of which only small quantities have been formed by the action of the HCl in the gastric juice. The intestinal juice has a *saccharase* or *invertase*, which disintegrates sucrose into fructose and glucose; a *maltase*, which transforms maltose into glucose; and in young mammals a *lactase*, which converts lactose into galactose and glucose.

[2] Grossman, M. I., *Physiol. Rev.*, **30**, 33, 1950.

[3] Aminopolypeptidase is an enzyme acting on polypeptides that have a basic N with at least one H. Carboxypeptidase, or carboxypolypeptidase, acts on polypeptides that have a free carboxyl but no free amines. Polypeptidases hydrolyze polypeptides; they act on the peptide bond next to the free amine. Dipeptidase disintegrates dipeptides made up of natural amino acids.

The Secretion of Intestinal Juice

There is almost general agreement that no secretion flows from an intestinal fistula in response to tasting and swallowing food. On the other hand, mechanical stimulation of the fistula provokes an abundant secretion. Local electrical stimulation and the local application of certain chemical substances also provoke secretion. Local stimulation is efficacious even after the intestine has been denervated; for this reason it is supposed that local stimulation produces its effects through reflexes taking place in Meissner's intramural plexus, or by a hormonal mechanism.

Vagal stimulation seems to produce enteric secretion.[1] Sympathectomy is followed by an abundant flow of "paralytic" secretion. In normal conditions, therefore, the sympathetic probably inhibits intestinal secretion.

Parenteral administration of several drugs (histamine, pilocarpine, eserine, and secretin) is followed by secretion of intestinal juice.

A substance, which is not secretin, has been extracted from the intestinal mucosa. The injection of this substance, called "enterocrinin," provokes an abundant secretion of enteric juice.[2] Conclusive evidence that enterocrinin is a specific hormone, which regulates intestinal secretion, has not yet been obtained. Concentrated preparations of enterocrinin with high potency have been obtained.[3]

In normal conditions the main stimulus of intestinal secretion is the local effect of mechanical stimulation and chemical agents found in the chyme.

THE BILE

The bile can be considered as both an excretion and a secretion. It is an excretion because it serves to eliminate the bile pigments, which result from the disintegration of hemoglobin, and some organic or mineral substances, together with certain drugs used therapeutically. It is a secretion because of its important digestive function. The liver produces bile continuously, but the presence of Oddi's sphincter and the gall bladder allows it to be poured intermittently into the intestine. Some animals, *e.g.*, the rat and the horse, do not have a gall bladder; this lack is compensated, in part, by the greater capacity of the bile ducts. The walls of the gall bladder, and in a lesser degree those of the ducts, secrete mucus and absorb water, so that storage of the bile results in its concentration.

Methods of study. Several surgical methods for permanent fistulization of the bile ducts have been devised. A catheter can be introduced into the common bile duct, or the area of the duodenal mucosa containing the ending of this duct (Vater's ampulla) can be transplanted to the skin. In man a temporary bile fistula, made with the purpose of evacuating the bile, is frequently used in the treatment of biliary disease. Duodenal catheterization by mouth is also commonly used to collect the duodenal contents.

Physical Properties of Bile

The color of the bile varies with its concentration and the pigments it contains. Hepatic bile is golden yellow or orange colored in man. The bile in the gall bladder is darker. The specific gravity of hepatic bile is approximately 1.008; that of the bile in the gall bladder can be up to 1.050. The osmotic pressure of hepatic bile is approximately that of blood (freezing point, −0.56 to −0.61°C.). Hepatic bile is slightly alkaline (pH 7.3 to 7.7) and that of the gall bladder is usually slightly acid (pH 6 to 7).

Chemical Composition of Bile

The bile obtained directly from the liver is less concentrated than gall-bladder bile. The principal components of bile are mucin, bile salts, bile pigments, lecithin, and cholesterol. Bile salts are the only substances of importance in digestion.

The bile salts. These are complex mixtures of the sodium salts of taurocholic and glycocholic acids. These acids are formed by combination of taurine and glycine respectively with one of the cholic acids (cholic, desoxycholic, and lithocholic acids). Cholic acid has a chemical structure similar to that of cholesterol, and it has recently been demonstrated that it is formed from cholesterol in the liver.[1] Taurine is formed from cystine. Glycine is an amino acid that can be synthesized by the organism.

Table 32. Composition of Human Bile

Constituent	*Hepatic bile, %*	*Vesicular bile, %*
Water	97.48	83.98
Mucin and pigments	0.53	4.44
Bile salts	0.93	8.70
Fatty acids (soaps)	0.12	0.85
Cholesterol	0.06	0.87
Lecithin	0.02	0.14
Mineral salts	0.83	1.02

Source: Hammarsten.

Bile salts lower the surface tension of solutions and thus further the emulsification of fats in the duodenum. The salts of desoxycholic acid also help dissolve many substances normally insoluble in water (fatty acids, lecithin, cholesterol, etc.). This "hydrotropic" effect is of great importance in the digestion and absorption of fats.

The bile salts excreted into the duodenum are reabsorbed and carried by the portal blood back to the liver, whence they are again excreted. Bile salts given by mouth can be almost completely recovered in the bile; they are therefore totally reabsorbed. This enterohepatic circulation of bile salts represents a great economy of effort for the organism. Nevertheless when the bile is lost through a biliary fistula, the liver continues to produce bile salts. Nothing is yet known about the factors that regulate the production of bile salts.

Bile pigments. These substances are responsible for the color of the bile. The golden yellow color in man is given by bilirubin, the principal pigment, and the green color by biliverdin. Biliverdin is a product of oxidation of bilirubin, and it can be found in vesicular bile. In the toad, biliverdin is the only pigment in the bile, so the accumulation of bile pigments in the blood following the obstruction of the common bile duct

[1] Bloch, K., B. N. Berg, D. Rittenberg, *J. Biol. Chem.*, **149**, 511, 1943.

causes the tissues to take on a greenish color instead of the yellow color typical of jaundice in mammals.[1]

The bile pigments are formed in the reticuloendothelial cells of the liver and other parts of the body in the process of disintegration of hemoglobin. Injection of hemoglobin or an excessive destruction of red blood cells causes an increase in the formation of bile pigments, which pass into the blood and are then excreted by the liver into the bile.

Bilirubin is reduced in the intestine by the action of bacteria, and is converted into urobilinogen, which is in part eliminated in the feces as stercobilinogen. A smaller amount of urobilinogen is reabsorbed and fixed by the liver, whence it goes to the blood and is excreted by the kidney. Stercobilinogen and urobilinogen are easily oxidized (in the gut or the renal excretory tubes), and thus stercobilin and urobilin are produced (see Chap. 4).

Normally up to 0.6 mg. of urobilinogen and urobilin are eliminated daily. The excretion of larger quantities is a sign of liver insufficiency, as it shows that there is a diminished capacity of the liver to retain this substance after reabsorption from the gut.

Cholesterol. Cholesterol is more readily soluble in bile than in water, because of the action of bile salts. It appears in high concentration in bile. Cholesterol is excreted with the bile into the duodenum, where it facilitates emulsification and absorption of fats and other lipids. Part of it is reabsorbed, but part is transformed into coprosterol by the intestinal bacteria and is eliminated in the feces.

The Action of Bile in Digestion

Action on fats. The favorable effect of bile in the digestion and absorption of fats is due to the bile salts and is of considerable importance. The activity of pancreatic lipase is increased several times by the presence of bile. This effect is due to the lowering of the surface tension by bile salts, which furthers the emulsification of fats; it is also due to the hydrotropic effect of bile salts, which increases the solubility of the fatty acids and soaps (even calcium salts, which are insoluble in water) that are produced by the digestion of fats. Bile also increases the effect of pancreatic lipase on dissolved substances, perhaps because in some way it helps the union of enzyme and substrate. The absorption of soaps and fatty acids is favored by the solvent action of bile. Cholesterol, the fat-soluble vitamins D, K, and E, and carotene need the presence of bile in the intestine in order to be absorbed.

An antiseptic or bacteriostatic action on the intestinal flora has been attributed to bile.

Action on intestinal motility. Obstruction of the biliary ducts is accompanied by a diminished intestinal motility. This might be due either to the lack of bile in the intestine or to the retention of bile salts or other bile constituents.[1] The administration of bile increases intestinal motility.

The Secretion of Bile

The secretion of bile by the liver is a continuous process, and it must be distinguished from the evacuation of bile into the intestine, which takes place intermittently.

The continuous secretion of bile is not dependent on nervous activity, as it is not suppressed by denervation. Nevertheless stimulation of the vagus increases and stimulation of the sympathetic nerves inhibits bile secretion.[2] Fasting and the loss of bile through a fistula diminish the secretion of bile. If a manometer is placed in the common bile duct, the pressure gradually rises to 250 to 300 mm. of bile and remains there. Secretion ceases at this pressure and jaundice appears. In normal conditions when the pressure reaches 50 to 70 mm. the bile flows through the cystic duct into the gall bladder. A normal adult man secretes 15 cc. of bile per kilogram of body weight every 24 hr.—about 1,000 to 1,100 cc. in a man weighing 60 to 73 kg.

The amount of bile secreted by the liver is increased by several substances given by mouth or injected into the blood stream. These substances are called choleretics.[3] Bile salts and bile acids are the most potent of all choleretics. The administration of 10 gm. of taurocholic acid, by mouth or injection, is followed by a rise in bile

[1] Cabello, J., *Rev. Soc. argent. de biol.*, **19**, 81, 1943.

[3] The term "cholagogue" (Greek, χολή, bile, and ἄγειν, to conduct) has long been used to signify an agent that increases the flow of bile by an increase either in the bile secreted or in that evacuated. More recently its significance has been limited to a greater evacuation of bile, and the term "choleresis" (Greek χολή, bile, and ερησις, removal) serves to indicate an increase in the bile secreted by the liver.

secretion that lasts over 24 hr. Secretin and stimulation of the vagus nerve also increase bile secretion. Among foodstuffs the most effective choleretics are fats, fatty acids and soaps, and the products of protein digestion. Atophan, eserine, and pilocarpine are also choleretics.
FIG. 177. Pressure in the common bile duct. On the left, pressure scale in cm. H_2O. Between the arrows, 25 cc. of milk, cream, and egg yolk (Boyden's meal) is introduced into the duodenum. Lower tracing, time in minutes. (*After Royer, M., and F. J. Manfredi, Rev. Soc. argent. de biol., vol. 20, p. 232, 1944.*)

Bile secretion is diminished by sugar in the diet, by fasting, by the stimulation of the sympathetic nerves, by the injection of adrenaline or morphine, and by anesthetics.

STORAGE AND EVACUATION OF BILE

The liver pours the bile into the intrahepatic ducts, which end in the hepatic ducts; these join to form the common bile duct. The cystic duct, which comes from the gall bladder, also ends in the common bile duct. The gall bladder is a reservoir in which bile is accumulated, modified, and concentrated during the intervals between digestive periods. The common bile duct ends next to Wirsung's pancreatic duct in Vater's ampulla in the duodenum. Royer and Solari[1] have shown that a dilatation of the end of the common bile duct, forming Vater's ampulla, occurs only in exceptional cases. The radiographic study of the duct filled with an opaque substance shows it ending in a beveled edge. Sometimes Wirsung's duct has a separate opening into the duodenum. As it passes through the intestinal wall, the common bile duct is surrounded by smooth-muscle fibers, which can close the duct when they contract. The opening of the duct into the ampulla is surrounded by a ring of smooth-muscle fibers which form Oddi's sphincter.

The liver secretes bile continuously during the intervals between the digestive periods. In dogs in the basal state the pressure in the common bile duct is 20 to 40 mm. H_2O, with rhythmical oscillations.[1] When the gall bladder empties, the pressure in the duct increases rapidly (Fig. 177). The sphincter of Oddi is in a state of tonic contraction, which can resist pressure up to 300 mm. H_2O. This tonic contraction serves to prevent the flow of bile into the gut and the entrance of the acid chyme and intestinal bacteria into the bile duct.

When the pressure within the duct rises to between 50 and 70 mm. H_2O, bile flows through the cystic duct into the gall bladder.

The gall bladder is a reservoir that contains about 50 cc. in man. There the bile is concentrated by the absorption of salts and water, and mucus secreted by the cells of the mucosa is added to it. The bile in the gall bladder is about 10 times as concentrated as bile newly secreted by the liver; therefore the 50 cc. contained in the gall bladder is the equivalent of 500 cc. of hepatic bile.

The arrival of the chyme into the duodenum provokes relaxation of Oddi's sphincter, contraction of the gall bladder, and probably also contraction of the bile ducts. Bile is thus evacuated into the gut. Afterward Oddi's sphincter contracts, the gall bladder relaxes, and the evacuation of bile ceases. These periods alternate during the first hours of digestion.

Cholecystography and duodenal catheterization. There are two principal methods for exploring gall-bladder function in man: cholecystography (the Graham-Cole test) and duodenal catheterization (the Meltzer-Lyon test).

Cholecystography consists in the x-ray examination of the gall bladder. A substance that

[1] ROYER, M., and A. V. SOLARI, *Gastroenterology*, **2**, 180, 1944.

[1] ROYER, M., and F. J. MANFREDI, *Rev. Soc. argent. de biol.*, **20**, 232, 1944.

is eliminated by the liver and therefore passes into the gall bladder (tetraiodophenolphthalein or tetrabromophenolphthalein) is given by mouth or injected intravenously. As the bile is concentrated in the gall bladder the concentration of the substance, which is opaque to x-rays, also increases, so the gall bladder is visualized in the x-ray film. The shape, size, and position of the gall bladder can thus be established. The ingestion of emulsified fats (egg yolk, cream), and to a lesser degree that of protein, cause the evacuation of the gall bladder in 1½ hr., as can be seen by taking a series of x-ray films.

In abnormal cases the bladder cannot be visualized with this method for one of the following reasons: (*a*) insufficient elimination of the drug by the liver; (*b*) incontinence of Oddi's sphincter; (*c*) obstruction of the cystic duct or of the gall bladder; (*d*) insufficient concentration in the gall bladder.

Duodenal catheterization consists in having the subject swallow a rubber tube of adequate diameter and length and passing it into the duodenum, the contents of which are drawn off with a syringe.

A few cubic centimeters of a solution of 33 per cent magnesium sulfate, or of olive oil, injected into the gut through the catheter, provokes a flow of bile and the evacuation of the gall bladder. At first a yellow-colored bile (bile A) coming from the liver is obtained; then a dark green, viscous bile (bile B), coming from the gall bladder; and finally again yellow bile from the hepatic ducts. The absence of B bile has a significance similar to that of the absence of visualization of the gall bladder, *i.e.*, it means that this organ is not functioning normally.

The motility of the gall bladder. The gall bladder has two different types of contractions: (*a*) tonic contractions, which increase the pressure within it up to 300 mm. H_2O and last 10 to 30 min. or even longer; (*b*) rhythmic contractions at the rate of two to six per minute. The gall bladder has also a postural tonus, by which is meant the tendency to recover the resting pressure after it has been altered by any cause. Tonic contractions can appear spontaneously or as a consequence of nervous or chemical stimuli.

The vagus nerve and the sympathetic nerves have motor fibers going to the gall bladder; the sympathetic nerves also have inhibitory fibers. The vagus is predominantly the motor nerve and the sympathetic nerves are predominantly inhibitory. Several drugs act on the motility of the gall bladder;[1] sympathomimetic drugs (adrenaline) relax the gall bladder and parasympathomimetic drugs (acetylcholine, pilocarpine) contract it. Atropine suppresses the effect of the parasympathomimetic drugs. Cholecystokinin (see below) also provokes contraction of the gall bladder.

The mechanism of bile evacuation. The evacuation of bile into the duodenum is dependent on several factors. The most important are the contraction of the gall bladder, the condition of Oddi's sphincter and of the duodenal musculature, and choleresis.

The principal stimulus of bile evacuation is the ingestion of food. Fats are the most efficacious; proteins are also active, while carbohydrates are much less so. Among the fats, egg yolk is the most potent. Olive and other oils, cream, etc., also show activity.[2] Acid in the duodenum provokes evacuation of the gall bladder.

Boyden[3] has demonstrated the intermittent evacuation of bile in man. After a meal there are alternate periods of contraction and relaxation in the gall bladder. Three phases can be distinguished in the periods of contraction:

1. An initial response commences 1 min. after the ingestion of food and lasts 2 min. It may be due to relaxation of the sphincter and contraction of the gall bladder by a psychic reflex, or to the arrival of food to the stomach or duodenum.
2. A pause of 2 min. follows the initial response. It is probably due to the recovery of tonus by Oddi's sphincter.
3. The main discharge then takes place. It lasts 6 to 60 min., and half to two-thirds of the contents of the gall bladder is evacuated.

A period of rest follows, lasting 5 to 45 min. These alternating periods are repeated several times until the gall bladder is completely emptied.

In man morphine increases the tonus of Oddi's sphincter; magnesium sulfate is supposed to re-

[1] Houssay, B. A., and H. H. Rubio, *Rev. Soc. argent. de biol.*, **8**, 370 and 379, 1932.

[2] These substances must pass into the duodenum before they act. Sometimes they remain for a long time in the stomach, and therefore their action on the gall bladder is delayed.

[3] E. A. Boyden, *Anat. Rec.*, **40**, 147, 1928.

lax it. In the dog opiates diminish the resistance of Oddi's sphincter.[1]

A reflex mechanism for evacuating the gall bladder has also been suggested. Some workers describe a mechanism of reciprocal innervation by means of which, on the ingestion of food or the arrival of acids or salts into the duodenum, a reflex is started that produces relaxation of Oddi's sphincter and contraction of the gall bladder. Conclusive evidence for this statement is still to be obtained.

Definite proof has been given that the denervated gall bladder, or a grafted gall bladder, can contract and evacuate its contents in response to the introduction of acids or fats into the duodenum. Contraction of the gall bladder is due to a hormone, which is similar to, but not identical with, secretin.[2] Ivy and Oldberg[3] have named it "cholecystokinin." Acids and the products of the digestion of fats introduced into the duodenum form or release this hormone, which passes into the blood stream and stimulates the contraction of the gall bladder.

THE MOTILITY OF THE SMALL INTESTINE

Methods of study. Several methods have been used in the study of the movements of the intestine: (*a*) direct observation or cinematography of the intestines, either after opening the abdomen with the animal submerged in saline solution, or else through a window in the abdominal wall; (*b*) direct observation or graphic registration of the movements of an intestinal loop transplanted out of the abdomen and covered by a thin cuff of skin (Ivy); (*c*) observation with x-rays after ingestion of an opaque meal; (*d*) the introduction of balloons into the gut by mouth, by rectum, or through fistulas, for registration of changes in intra-intestinal pressure; (*e*) registration of the movements of isolated strips of intestine.

a

c
Fig. 178. Diagram of segmentation movements in the small intestine: *a*, at rest; *b*, first stage; *c*, second stage.

Movements of the Small Intestine

It is usual to describe three types of movements in the small intestine: (*a*) rhythmic movements of segmentation; (*b*) peristalsis; (*c*) pendular movements.

Rhythmic movements of segmentation. Cannon considers this type of movement as the most constant and fundamental form of intestinal motility. A quiescent loop of intestine suddenly shows a regular series of annular constrictions, which divide it into ovoid segments. Shortly afterward, a constriction appears in the most dilated part of each segment and simultaneously the first constrictions disappear (Fig. 178). This alternation is repeated six to ten times per minute in man. The intestinal contents do not progress; they remain within the loop. These movements serve (*a*) to mix the contents with the intestinal juices; (*b*) to bring the intestinal contents into contact with the villi; (*c*) to evacuate the lymphatics and veins of the intestinal wall and thus favor local circulation.

The movements described are not dependent on the intrinsic or extrinsic innervation of the gut; they can be observed after complete denervation, and also in strips of intestinal muscle in which the nerve plexuses have been removed. Nicotine and cocaine, drugs that paralyze nervous activity, do not modify these movements. Rhythmic segmentation, therefore, is apparently myogenic.

[2] Agren, G., *Skandinav. Arch. f. Physiol.*, **81**, 234, 1939.

[3] Ivy, A. C., and E. Oldberg, *Am. J. Physiol.*, **86**, 599, 1928.

According to Alvarez[1] the frequency and force of contractions, intestinal tone, and irritability diminish progressively from the duodenum to the ileocolic valve, coinciding with a gradual decrease in the metabolic activity (oxygen consumption and CO_2 production) of the intestinal muscle as the distance from the pylorus increases. This parallelism between muscular activity and metabolic exchanges led Alvarez to put forward his theory of the existence of a metabolic gradient in the intestine, on which its physiologic activity and peristaltic polarity would depend.

Peristaltic movements. These movements are the same as those of peristalsis already described in the esophagus and the stomach; they consist in waves of contraction that progress along the intestine. There are two types of peristalsis: (*a*) slow waves, described by Bayliss and Starling,[2] which travel at the rate of 2 cm. per min. for a short distance; (*b*) fast waves, which progress at speeds up to 25 cm. per min. and travel a long way down the intestine, sometimes its whole length. The fast waves have been named *peristaltic rushes* by Alvarez.

Bayliss and Starling,[3] in their classic observations on peristalsis, came to the conclusion that slow waves are produced by a reflex caused by the distention of the intestine, in which Auerbach's plexus plays a part. They consist in contraction of the circular muscle above the distention, with relaxation in the immediately distal part of the intestine (*myoenteric reflex*). Contraction and relaxation simultaneously progress as a wave for a short distance. Stimulation of the intestine (*e.g.*, by pinching) is followed by contraction above and relaxation below the stimulated point. This reflex takes place even after cutting the extrinsic nerves of the intestine, but is suppressed by the local application of cocaine or nicotine. Bayliss and Starling believed this was the typical motor activity of the intestine (*the law of the intestine*). Later Alvarez found that this type of activity is the only one observed after denervation, but in the normal organism the other types of activity are more commonly seen. Peristaltic waves push forward the intestinal content. It has been proved that the bolus

[1] Alvarez, W. C., *Am. J. Physiol.*, **35**, 177, 1914.
[2] Bayliss, W. M., and E. H. Starling, *J. Physiol.*, **24**, 99, 1899.
[3] Bayliss, W. M., and E. H. Starling, *J. Physiol.*, **26**, 125, 1901.

progresses in a spiral fashion, probably because of the arrangement of the muscular fibers of the intestine.

Peristaltic rushes occur with greater frequency and travel a longer distance when the whole intestine is active than when it is in a quiescent state. The best way to stimulate a peristaltic rush is to drink a certain amount of fluid. Sometimes swallowing movements are enough to start a rush; at other times, the passage of chyme into the duodenum or a peristaltic wave from the stomach starts a peristaltic rush in the small intestine. This type of movement is apparently due to a reflex.

Pendular and other types of movement. Pendular movements are due to annular constrictions that travel up and down a short length of the bowel. These movements are repeated with a frequency of 10 to 20 per minute; they do not push the contents along the intestine, but serve to mix them with the digestive juices and to bring them into contact with the intestinal villi.

Beside the three principal types of movement already described (segmentation, peristalsis, and pendular movements) there are others, such as tonic waves, which progress slowly along the intestine, a contraction of systolic type that occurs only in special conditions, and antiperistaltic waves.

Coordination of intestinal movements. Little is known about the mechanisms which integrate and coordinate the movements of the small intestine in such a manner that one type of movement follows another in an orderly sequence, thus assuring the normal progress of digestion and absorption. Many years ago Cannon[1] observed that foodstuffs of different kinds advanced along the intestine at different rates, yet digestion and absorption were equally complete when the intestinal residue arrived at the final part of the ileum. Gregory[2] has studied this problem in dogs with a Thiry-Vella fistula in the jejunum, after the animals had recovered from the operation, so that they could be examined without anesthesia. After a prolonged period of fasting the intestinal loop was in a "basal" condition in which alternating periods of activity and quiescence were observed. After feeding, tone and activity were increased for several hours. This is a reflex response, mediated

[1] Cannon, W. B., *Am. G. Physiol.*, **12**, 387, 1904.
[2] Gregory, R. A., *J. Physiol.*, **111**, 119, 1950.

by the vagi, which arises in (*a*) cephalic receptors (sham feeding provokes it), and (*b*) the stomach, when it is distended by food. The composition of the intestinal content also conditions the tone and movements of the loops: bile salts, the products of protein digestion, hypertonic saline, and acids increase tone and motility. These effects are not suppressed by denervation or by blocking the ganglia with tetraethylammonium. Application of a local anesthetic suppresses the response, which seems, therefore, to be dependent on local nervous activity in the intestinal wall.

Polarization. Antiperistaltic waves are frequently observed in the duodenum and also in the last segment of the ileum; in other parts of the intestine they are seldom seen. Mall[1] and others have reported that if a sufficiently long segment of intestine is cut out and then reunited to the intestine with the ends inverted, this segment becomes a barrier that stops the progress of the intestinal contents in spite of the continuity and patency of the intestinal canal. The intestine is therefore "polarized" in the sense that fluids and solids are made to progress in one direction only. The cause of this polarity, according to Bayliss and Starling, resides in the "law of the intestine"—the fact that when a stimulus acts on the intestine there is contraction above the point stimulated and relaxation below. Alvarez maintains that the metabolic gradient is the underlying factor of intestinal polarity.

The action of drugs.[2] Drugs modify intestinal tonus and peristalsis. Atropine, banthine,[3] and morphine diminish, and prostigmine and pitressin increase, the strength of contraction in the jejuno-ileum of man. The first three drugs retard the passage of the contents along the gut; the last two accelerate it.

By means of radiologic studies in dogs it has been demonstrated that ergotamine and prostigmine accelerate the passage along the intestine, while atropine and ephedrine retard it.[4]

The influence of innervation. Whatever may be the cause of intestinal polarity, it is independent of the extrinsic innervation. Intestinal movements are not significantly modified by the complete denervation of the small intestine. Rhythmic segmentation is myogenous, and slow peristalsis is apparently due to reflexes in the Auerbach plexus.

Auerbach's plexus lies between the circular and longitudinal muscle layers. It has many ganglia and connections with Meissner's plexus, which is situated in the submucosa. The vagus nerve ends on the ganglion cells of Auerbach's plexus. Stimulation of the vagus produces, after a short period of inhibition, an increase in tonus and peristalsis. Section of the vagus decreases intestinal tonus but has no influence on peristalsis; therefore its action is not continuous on this last type of movement.

The majority of sympathetic fibers going to the intestine travel in the minor splanchnic nerves to the celiac and superior mesenteric ganglia, where the postganglionic fibers to the intestine commence. Stimulation of the sympathetic, or injection of adrenaline, inhibits peristalsis and diminishes intestinal tonus. Section of the splanchnic nerves is followed by an increase in peristalsis; therefore the sympathetic has a continuous inhibitory action on this type of motility. There is some proof that ileus paralyticus (intestinal paralysis) occurring in peritonitis is due to stimulation of the splanchnics.

The Movements of the Duodenum

The movements of the duodenum deserve special consideration. The duodenal cap is passively distended by the chyme that passes through the pylorus. The duodenal cap then contracts, and its contents are passed on to the second and third parts of the duodenum. These parts have peristaltic movements that send the chyme forward, but there are also antiperistaltic movements that send it back into the duodenal cap and even into the stomach. Once the contents have reached the fourth part of the duodenum, they do not go back.

The Emptying Time of the Small Intestine

The chyme reaches the last part of the small intestine in about three and a half hours after the commencement of gastric evacuation. It stays there for a certain time, and rhythmic segmentation of the bowel helps the absorption

of foodstuffs. Peristalsis is not very active in this last part of the ileum, but it is increased by the ingestion of food (gastroileal reflex). Thus the contents pass on to the colon.

Where the ileum ends in the cecum, for a length of about 2 cm. the muscular layer thickens and forms a sphincter. This ileocolic sphincter relaxes before a peristaltic wave and then contracts, thus avoiding regurgitation of the contents of the cecum into the ileum. Usually the sphincter resists a pressure of 40 to 50 cm. H_2O, but in some cases it is overcome by pressures lower than these (incontinence).

The sphincter is not controlled by the vagus. Stimulation of the splanchnic nerve provokes strong contraction of the sphincter.

The ileocecal sphincter has a double function; it prevents the passage of the contents of the cecum into the ileum, and it prevents a too-rapid emptying of the ileum into the cecum, thus giving time for complete digestion and absorption.

CHAPTER 39

The Large Intestine

THE LARGE INTESTINE[1] consists of the cecum and the appendix, the colon, the rectum, and the anal canal. Its principal function is to form, transport, and evacuate the feces. The shape and size of the colon differ considerably from one species to another. Carnivora have a short colon and a small cecum; the latter in some cases is missing. Herbivora have a long colon and a large cecum full of foodstuffs. This difference is due to the fact that in herbivora the bacteria of the large intestine play an important part in digestion; they dissolve the cellulose covering of the food and thus set free the nutritive contents. In carnivora digestion and absorption are almost complete by the time the contents arrive at the cecum. The large intestine can absorb only water, glucose, and salts. The large intestine of man resembles that of carnivora in length, but it has the haustral segmentation seen in herbivora.

Compared with other parts of the digestive tract the large intestine differs by its capacity, its distensibility, and the fact that its contents are held back for a considerable time.

Absorption, secretion, and excretion. One of the important functions of the large intestine is the absorption of water. The contents of the cecum and the ascending colon are almost liquid. The greater part of the remaining water content and some soluble substances are absorbed there, but the capacity to absorb fluids and crystalline substances exists all along the large intestine, down to the sigmoid and rectum. This property is used in therapeutics to give by rectum water, minerals (salt, calcium, iron), carbohydrates (glucose), and drugs (atropine, mercurial diuretics, salts of mercury, etc.).

The large intestine secretes a thick alkaline fluid (pH 8.4), rich in mucus. A more fluid secretion is obtained by mechanical irritation of the bowel, stimulation of the pelvic nerve, and injection of pilocarpine.

Stimulation of the sympathetic and injection of atropine inhibit this secretion. The juice secreted by the large intestine has no enzymes and its function appears to be one of lubrication, thus facilitating the progress of the feces and protecting the mucosa.

The large intestine has an excretory function; thus heavy metals (Ca, Mg, Hg) and certain drugs used in therapeutics (*e.g.*, arsenicals) are excreted in great part through the large intestine.

Innervation of the large intestine. Two parts must be distinguished in the large intestine, with respect both to its innervation and to its movements: (*a*) a proximal part (the cecum, the ascending colon, and part of the transverse colon); (*b*) a distal part (left half of the transverse colon, the descending colon, and the ileopelvic colon).

The proximal colon is innervated by sympathetic and parasympathetic fibers from the superior mesenteric plexus; the former are inhibitory and the latter motor. The sympathetic fibers for the distal colon arise in the upper lumbar roots and travel through the intermesenteric and inferior mesenteric plexuses and their pelvic splanchnic branches. The parasympathetic fibers originate in the second, third, and fourth sacral nerves and reach the colon through the hypogastric plexus.

According to the findings of Ivy and his coworkers, the nerve fibers that go to the colon through the pelvic nerve are cholinergic, and those which travel in the hypogastric nerve are adrenergic.

The movements of the large intestine. The large intestine is loose in the abdomen so that its position varies with posture, with respiratory

[1] HARDY, T. L., *Lancet*, 1, 519, 1945.

movement, and with the degree of its distention. The more movable parts are the transverse and pelvic colon. The cecum, the ascending colon, and the hepatic flexure are less movable. The splenic flexure, the descending colon, and the rectum are relatively fixed structures.

The time taken by the contents of the intestinal tract to reach the ileocolic sphincter is extremely variable (30 min. to 5 hr.). Approximately 3½ hr. after gastric evacuation has begun, or even before if a second meal is taken (gastroileal reflex), the contents of the small intestine commence to pass into the cecum. The cecum and the ascending colon are passively filled with a fluid mass, which pours through the ileocolic sphincter in small jets. In 24 hr. approximately 450 cc. of water enters the cecum; the feces of a normal subject contain about 80 cc. of water and 35 gm. of solids; therefore the proximal part of the colon absorbs around 370 cc. of water.

In some animals (cat, rabbit) peristaltic movements, which carry the contents up into the first half of the transverse colon, are seen, followed by antiperistaltic movements which send them back into the cecum. In man the movements of the colon[1] are less frequent, and therefore difficult to observe by x-rays. There are two types of movement in the large intestine, propulsive and nonpropulsive movements, beside changes in tonus. Contraction of one segment makes the contents go forward only when the adjacent distal segment is relaxed; the length traveled by the propulsive wave depends on the coordination of adjacent segments. Extracts of the posterior lobe of the hypophysis (vasopressin, pitressin), prostigmine, and ergotamine increase the propulsive motility of the colon. Morphine increases the tonus and the nonpropulsive motility, but diminishes the propulsive activity. Atropine and banthine inhibit the motility of the colon. Usually the movements of the large intestine are few, and whatever their type, the feces make little or no progress. These movements churn the contents and help the absorption of water. Nevertheless, a few times a day, after a meal (gastrocolic reflex) or in the course of defecation, a strong contraction begins in the transverse colon and travels in a wavelike manner toward and down the descending colon, propelling into the pelvic colon the whole contents of the distal part of the large intestine.

[1] Atkinson, A. J., H. F. Adler, and A. C. Ivy, *J. A. M. A.*, **121**, 646, 1943.

A meal containing a substance opaque to x-rays, *e.g.*, barium, can be followed down the digestive tract, and the time taken to reach the different parts noted.[1] Usually 3½ hr. after the ingestion of the opaque meal the cecum begins to fill—a process which is completed by the seventh hour. The cecum and the ascending colon are filled, but the mass does not go farther than the hepatic flexure. Between the seventh and the eighth hours the transverse colon is filled as far as the splenic flexure. This flexure apparently presents an obstacle to the advance of the intestinal contents. The mass that fills the cecum and the ascending and transverse colon remains in these segments up to the twentieth hour after ingestion. During this time nonpropulsive movements are observed which churn the contents and facilitate the absorption of water. Around the twentieth hour a strong contraction of the colon begins. The transverse colon, which hangs loose in the abdomen, straightens out, the splenic flexure is rounded, and the contents are moved into the descending colon (mass peristalsis). All these movements last 1 to 4 sec. The colon from below the hepatic flexure (cecal sphincter?) up to the splenic flexure is thus emptied. Sometimes there is no mass peristalsis and the transverse colon empties itself in several stages, at more or less long intervals.

The opaque mass then fills the descending colon and sometimes part of the sigmoid. Around the twenty-fourth hour after a meal there is mass peristalsis in the descending and pelvic colon, and the rectum is filled. Defecation follows soon after (Fig. 179).

DEFECATION

Usually the feces are stored in the pelvic colon until defecation takes place. At the junction of the pelvic colon and the rectum there seems to be an obstacle to the progress of the feces; according to some observers there is a definite sphincter at this level (pelvirectal sphincter). Only when this obstacle is overcome by a movement of mass peristalsis and the feces distend the rectum (a pressure of 30 to 40 mm. Hg is enough) is a perineal sensation felt, which awakens the desire to defecate. The weight of the feces in the sigmoid does not provoke this

[1] Becker, R., and A. Oppenheimer, "Normale und pathologische Funktionen der Verdauungsorgane im Röntgenbilden," Thieme, Leipzig, 1931.

desire, but gives a sensation of fullness localized above the pubis.

Defecation is a reflex. Distention or stimulation of the rectum by movements of the feces within it or in the anal canal, or by other means, provokes reflexly a strong wave of mass peristalsis, contraction of the rectum, and relaxation of the internal and external anal sphincters, thus emptying the large intestine from the transverse colon down. This emptying is helped by the simultaneous contraction of the diaphragm and of the abdominal muscles, which increases abdominal pressure, and that of the levatores ani and other perineal muscles, which sustain the perineum and help to evacuate the last remaining portions of the rectal contents.

The afferent paths of the reflex travel along the pudendal and pelvic nerves. The efferent paths belong to the sympathetic and parasympathetic. The sympathetic fibers arise in the lumbar segments of the spinal cord and end in the inferior mesenteric and hypogastric ganglia, whence the postganglionic fibers go to the bowel in the lumbar colonic and hypogastric or presacral nerve. The impulses traveling in these fibers have a continuous inhibitory effect on the walls of the distal colon, and a motor effect on the internal anal sphincter. The activity of the distal colon increases when these fibers are cut; when they are stimulated, the colon relaxes. Stimulation also increases the tonus of the internal anal sphincter. The parasympathetic fibers arise in the sacral segments of the cord and form the pelvic nerve. They have a continuous motor effect. Section of the pelvic nerve relaxes, and stimulation increases, the motility of the distal colon. Stimulation of the pelvic nerve relaxes the internal anal sphincter. The external anal sphincter is a striated muscle under voluntary control; it is innervated by fibers of the pudendal nerve that originate in the sacral segments of the cord.

The spinal center of defecation is situated in the lumbosacral segments of the cord, principally in the second, third, and fourth sacral segments. Section of the cord above this level does not disturb defecation once the effects of spinal shock have passed (see Chap. 81). Destruction of the sacral segments is followed by fecal incontinence; nevertheless in some cases after a time a certain degree of automatic control of evacuation is recovered. A medullary center, situated in the floor of the fourth ventricle, near the respiratory and the vomiting centers, has

FIG. 179. Diagrams of the movements of the colon: *a*, roentgenographic picture 5 to 6 hr. after ingestion of a barium meal; *b*. 7 to 8 hr.; *c*, 12 to 20 hr.; *d*, around 20 hr.; *e*, 20 to 24 hr.; *f*, 24 to 26 hr. after the barium meal. The dotted line shows the direction of the movement and the amount of previous filling. (*Becker, R., and A. Oppenheimer, "Normale und pathologische Funktionen der Verdauungsorgane im Röntgenbilden," Thieme, Leipzig, 1931.*)

been described. The spinal centers that control the tonus of the sphincters can be inhibited by peripheral stimulation or by intense emotions (fear, etc.).

From the second year of life in human beings the reflex mechanism of defecation is under voluntary control, at least in the ordinary conditions of life.

The Feces

In man and carnivora the ingested foodstuffs are almost completely absorbed before they reach the cecum. The semiliquid mass that passes through the ileocolic sphincter consists mainly of the residue of the digestive secretions (gastric, pancreatic, and intestinal juices; mucus; and bile), epithelial cells, and leukocytes. A great part of the water in the contents that pass into the cecum is absorbed in the large intestine, where bacteria and certain solid substances are added. A semisolid paste is formed, called the feces or fecal matter.

Fecal matter is therefore more a product of the activity of the digestive tract than a residue of foodstuffs. The following facts are proof of this assertion: (*a*) there are no soluble carbohydrates or proteins in the feces; (*b*) after a meat meal there are no muscle fibers in the feces; (*c*) the nature of the diet, if it does not contain cellulose, has no influence on the chemical composition of the feces; (*d*) in complete fasting fecal matter is produced and its chemical composition is the same as in normal feeding; (*e*) if a loop of the bowel is tied between two ligatures, after a time it is filled with a soft pastelike substance similar to fecal matter.

Fecal matter is made up of water (65 to 75 per cent); nitrogen (3 to 5 gm. per cent), mostly bacterial and endogenous; lipids (lecithin, coprosterol, fatty acids, and a verys mall amount of neutral fats), also mostly endogenous; a large number of bacteria; some minerals (Ca, P, Mg, Fe); and the products of disintegration of the bile pigments (stercobilinogen and stercobilin).

Cellulose ingested with the food is not absorbed in the small intestine; in man the bacteria of the large intestine do not have much effect on it. Nevertheless it plays an important part in digestion, because by increasing the bulk of the feces it stimulates peristalsis, accelerates the passage through the digestive tract, and helps intestinal evacuation.

THE MICROBIAL FLORA OF THE DIGESTIVE TRACT[1]

Many species of microorganisms inhabit the digestive tract. In the mouth there are numerous microbes: enterococci, staphylococci, spirochetes, spirils, vibriones, amebas, actinomyces, etc. The stomach and the proximal part of the small intestine are sterile or contain few microorganisms (mostly those of lactic fermentation); this is due to the antiseptic effect of the strong acidity of the gastric juice. The last part of the small intestine has some bacteria, among which *Escherichia coli* predominates; many of these come from the large intestine. Anaerobic bacteria do not grow in the ileum; therefore products of putrefaction are not found in this part of the intestine.

The number of microorganisms in the large intestine is enormous. Cohendy[2] has studied quantitatively the microbial flora of human feces and has found that 1 mg. of feces contains 143,870,000 microorganisms; according to him, bacteria make up about two-thirds of the dry feces.

The microbes in the digestive tract live on the protein and carbohydrate in the food, acting on them by two processes called putrefaction and fermentation. In putrefaction protein is attacked by the anaerobic bacteria and disintegrated into a series of substances that have the typical odor of putrefaction: amines (ethylamine, thyramine, histamine); volatile acids; phenols (indol and skatol) derived from tryptophane by deamination and decarboxylation; paracresol and phenol derived from phenylalanine and tyrosine by similar processes; substances containing sulfur (H_2S); and gases (H, CO_2, CH_4). In man and in carnivora, putrefaction is due almost exclusively to the anaerobic bacteria of the large intestine.

Carbohydrates are disintegrated by fermentation into a series of substances. Sugars are broken down to lactic acid in the stomach and the first part of the small intestine by the action of several germs. This process is of importance in suck-

Also papers by Scheunert and Schlieblich, Rietschel and Hummel, and Magnus-Alseben in Bethe's "Handbuch der normalen und pathologischen Physiologie," **3**, 967, 1001, and 1027, Springer, Berlin, 1927.

[2] Cohendy, M., *Compt. rend. Soc. de biol.*, **60**, 415, 1906.

lings. In the last part of the small intestine other microorganisms also attack sugars and break them down into acids, alcohols, ketones, and gases.

Microbes play an important part in the digestion of cellulose. None of the digestive enzymes acts as a cellulase for the hydrolysis of cellulose. Nevertheless, cellulose, the principal food of the herbivora, can be utilized thanks to the action of microorganisms. The digestion of cellulose in animals is a "monopoly of bacteria." In herbivora the architecture of the digestive tract (rumen, cecum, colon) allows a prolonged retention of the foodstuffs and thus facilitates the action of microorganisms. In the feces of man *Bacillus cellulosae dissolvens* has been found.[1] Although it has a potent activity on cellulose, very little cellulose is digested in the large intestine of man.

The microorganisms in the digestive tract sometimes play an important part in the development of pathologic conditions, but they are also prominent in certain physiologic functions; *e.g.*, their participation in the synthesis of some of the vitamins has been well demonstrated. Shortly after birth the intestinal flora commences to develop, and the blood-coagulation time becomes normal as a result of the synthesis of vitamin K by intestinal bacteria. In herbivora, intestinal bacteria also synthesize thiamine, riboflavin, pyridoxine, pantothenic acid, biotin, folic acid, and nicotinic acid. Bacterial activity is an important source of these accessory food factors, indispensable to animal life. Vitamins originated in the bowel are not always totally absorbed. Thus in rats fed a diet free from vitamin B_1 (thiamine), this substance is synthesized in the intestine but is not absorbed in adequate amounts. If the animals have access to their feces they eat them, and the symptoms of avitaminosis do not appear or are considerably delayed; this proves that vitamin B_1 is produced by the intestinal bacteria in amounts sufficient to keep the animals free from symptoms. But if coprophagia is prevented avitaminosis soon appears; therefore the thiamine produced is not immediately absorbed in sufficient quantities.

Recent work has shown that in adult human beings intestinal bacteria synthesize thiamine, biotin, folic acid, pyridoxine, pantothenic acid, para-aminobenzoic acid, vitamin B_{12}, nicotine amide, and riboflavin, and that this source of these vitamins is sufficient for the needs of the organism.[1]

[1] KHOUVINE, *Ann. Inst. Pasteur*, **37,** 712, 1923.

Intestinal bacteria not only synthesize some of the indispensable vitamins; they can also destroy them. Vitamin C is destroyed by many of the microorganisms in the bowel (*Escherichia*, *Aerobacter*, *Salmonella*, *Eberthella*, *Streptococcus encapsulatus*, and *Vibrio*) when there is anaerobiosis.[2] Nicotinic acid is also destroyed by intestinal bacteria in anaerobic conditions; but the destruction is not as rapid and complete as that of ascorbic acid (vitamin C).[3] There is also evidence of the destruction of vitamin B_1 (thiamine) in the human intestine. These facts explain why, in the treatment of some cases of vitamin deficiency, better results are obtained when the vitamin is given by injection than when it is given by mouth.

SECTION FIVE

Metabolism and Nutrition

CHAPTER 40

The Material and Energy Exchanges of the Body

Definitions. Metabolism consists of the exchange of matter and energy between the organism and the environment, and also the material and energy transformations within the organism. At one time the terms "metabolism" and "nutrition" were considered synonymous, but now "nutrition" signifies the relation existing between the ingestion of food and metabolism, *i.e.*, the sum of the processes concerned in the growth, maintenance, and repair of the living body as a whole or of its constituent organs (Lusk). "Metabolism" is restricted to the energy and material transformations within the body.

General description. Metabolic processes can be considered from two points of view:

1. The material cycle, *i.e.*, changes undergone by substances in the body in the different periods of life—during growth, the equilibrium of the adult, and the involution of senescence.
2. The energy cycle, *i.e.*, transformations undergone by the chemical energy in the foodstuffs, until it is finally eliminated as heat in the resting animal, or as heat and work when the muscles are active.[1]

There are two fundamental processes in the metabolism of matter: (*a*) anabolism, or assimilation; (*b*) catabolism, or the disintegration of substances. Assimilation is the formation of the specific substances of the organism from absorbed substances. Catabolism consists of the processes of disintegration of substances in the tissues into simpler ones; the end products ar usually excreted.

Life is maintained by a continuous transfor mation of matter and energy, which are taken i with the foodstuffs. Food fulfills the followin functions: (*a*) it provides raw material for th formation of the mass and the specific substance of the body needed for growth, maintenance and repair of the results of the incessant wear an tear of the tissues; (*b*) it provides energy, whic the organism transforms in the course of it activity;[1] (*c*) it provides substances that regulat metabolism (vitamins, etc.).

Food is first submitted to digestive processes which convert colloidal nondiffusible substance into crystalloid diffusible ones, and comple foreign substances into simple ones, easily ab sorbed, which can be used for the formation o the specific substances of the organism. Thes nutritive substances are then absorbed and cir culate in the organism. Some are used up im mediately by the tissues; others are stored, some times after undergoing certain processes tha change them into forms suitable for storage. I the course of metabolism, residual or waste prod ucts are formed which are eliminated by th organs of excretion (kidney, intestine, skin, lung)

An outstanding feature of metabolism is th tendency to maintain an equilibrium. Thus th basal oxygen consumption and the fasting blood sugar level do not vary much from day to day and if any change does occur, the initial rate o

[1] In man there is no significant output of energy in other forms such as occurs in some animals, *e.g.*, electricity in electric fishes, light in certain insects, etc.

[1] This energy is used up by basal metabolism, by th specific dynamic action of foodstuffs, in work per formed by the organism, and in maintaining the bod temperature.

level is rapidly reestablished. This stability of metabolic processes is due to a complex aggregate of nervous and humoral factors which regulate these processes.

Several methods are used in the study of the metabolism of a substance: (*a*) the substance is administered, and its excreted end products are examined by chemical methods; (*b*) the substance administered is especially prepared with an isotope of one of its constituent elements, easy to detect by some physical character (weight, radioactivity) so that it can be followed in its passage through organic fluids and tissues and in the secretions and excretions of the body; (*c*) an organ, isolated from the rest of the body, can be maintained alive and functioning by perfusing it with whole blood or a nutrient fluid, and its metabolism can thus be studied; (*d*) respiratory and other metabolic processes of surviving slices of tissue, or of ground tissue, can be studied in Warburg's and other similar apparatus.

The use of isotopes. Remarkable results are being obtained in the study of the metabolism of animals, plants, and bacteria by the continuously increasing use of isotopes.[1] Isotopes are atoms of chemical elements which have the same number of planetary electrons as the "normal" atom but more or less neutrons in the nucleus. They have the same chemical properties, because these are dependent on the number of electrons, which is the same in all the atoms. The physical properties, on the other hand, are different because the atomic mass of each isotope differs from that of the "normal" atom because of the different number of neutrons in the nucleus. There are natural and artificial isotopes. Some are stable; others are radioactive. Deuterium or "heavy" hydrogen is a stable isotope. Its atomic weight is 2 (twice that of "normal" hydrogen) because its nucleus has one proton and one neutron, instead of only one proton.

Radioactive isotopes can be prepared by bombarding an atom in a cyclotron, or by bombarding a "normal" atom with neutrons in an atomic pile so as to eliminate one or more neutrons from its nucleus. The radiation these isotopes emit can be β or γ rays, or positrons. By measuring the intensity of radiation in a Geiger-Müller counter or some other electrometer, it is possible to detect and to estimate the concentration of the isotope. The stability of a radioactive isotope is measured by the time taken for its radiation to lose half its initial activity; this is known as the "half life." Thus P^{32} has a half life of 14.3 days, and K^{42} one of 12.4 hr. Isotopes do not lose their physical characteristics by taking part in chemical reactions, therefore they can be followed in the different products resulting from the chemical processes of the organism in which the substances they form part of are active. The most frequently used isotopes in biochemical studies are C^{14}, I^{131}, Fe^{59}, N^{15}, Na^{24}, K^{42}, P^{32}, Cl^{38}, Ca^{45}, and S^{35}. They can be obtained through the United States Commission on Atomic Energy.

The use of isotopes has brought about revolutionary changes in the knowledge of the photosynthesis of chlorophyll, and of the metabolism of proteins, fatty acids, carbohydrates and minerals in animals, plants, and bacteria. The knowledge of the processes of intermediate metabolism is being rapidly developed by the use of isotopes.

Material and energy balanes. The study of general metabolism consists in establishing the balance of all the substances or all the energy that enters into the organism and is eliminated from it. On the other hand, the special metabolisms of one particular substance (*e.g.*, calcium, iodine, water) can be made the object of a particular study. There is equilibrium in metabolism (*e.g.*, calcium equilibrium) when the output of the substance is equal to the intake. A positive balance signifies that there is a gain in substance or energy because the intake is greater than the output; when there is a negative balance, there is a loss of substance or energy because the output exceeds the intake.

Foodstuffs have a twofold function. Some can be oxidized by the organism, thus releasing chemical energy, which is finally converted into heat and work; others are the raw material for the building and repairing of tissues and organic fluids. Organic foods, such as carbohydrates, proteins, and fats, serve to build up the specific substances of the body and to provide energy; inorganic foods, such as water and salts, do not yield energy but are necessary for the formation and upkeep of the body fluids and tissues.

The material balance of the organism is established by measuring the intake of foodstuffs and oxygen on the one hand and on the other the excreta eliminated in the urine, in the feces, and through the skin and lungs.

ESTIMATION OF THE MATERIAL AND ENERGY BALANCE

Methods. The composition of foodstuffs is determined by chemical analysis. When experiments must be made with animals fed on a standard diet, a large quantity is prepared and a sample is analyzed; the food is then stored, in the refrigerator if necessary, and used as it is needed. Foodstuffs have been analyzed and the results published in tables. For practical purposes health officers and clinicians can establish approximately the composition of any diet by reference to these tables. Protein is measured by estimating the total nitrogen content by the Kjeldahl method and multiplying the result by 6.25 (proteins have on an average 16 per cent N, therefore 1 gm. N = 6.25 gm. proteins). Fats are estimated by the weight of the ether extract. Carbohydrates are measured by submitting the foodstuffs to hydrolysis with dilute acid, and then measuring the amount of reducing substances; the result is usually given in terms of glucose. Water is measured by drying the food at 100 to 110°C. (or by distilling it); the difference in the weight before and after drying gives the water content. Ash content is determined by weighing after calcination. Methods for the analysis of foodstuffs are being continuously improved.
Nitrogen is excreted in the urine (90 to 98 per cent), in the feces (2 to 10 per cent),[1] and through the skin (insignificant amounts). Carbon is eliminated by the lung (CO_2) and in the urine and feces; oxygen and hydrogen by the lung, in the urine, in the feces, and through the skin; and salts in the urine, in the feces, and through the skin. All the energy at the disposal of animal organisms comes from chemical energy in foodstuffs. This energy is released in chemical reactions which lead to oxidation of C and H, with the formation of CO_2 and H_2O, which are eliminated from the body. In a burning candle, oxidation takes place directly and energy (heat, light) is immediately set free. In the cells, oxidation is performed in stages; hydrogen and electrons are transferred from one substrate to another by a series of enzymatic reactions in which the heat of combustion is gradually released (see Chap. 34, Cell Respiration).

Bioenergetics is based on a material and an energy cycle:

1. Material cycle:

Foodstuffs burned } + Oxygen = { Urea and nitrogenous waste products; CO_2, water; Sulfates, phosphates etc.

2. Energy cycle:

Chemical energy in foodstuffs } + Oxygen → { Resting → Heat; Working → { Heat, approximately 78 per cent; Work, approximately 22 per cent

The energy balance is established by measuring the energy entering the organism (caloric value of food ingested) and the output of energy (heat and work). Energy is measured in calories. A calorie is the amount of heat needed to raise the temperature of 1 gm. (small calorie, cal.) or 1 kg. (large Calorie or kilogram-calorie, kg.-cal.) of water from 14.5 to 15.5°C. Work is easily converted into calories; 427 kg.-m. is the equivalent of 1 kg.-cal. (1 kg.-m. = 0.0024 kg.-cal.). One kilogram-calorie (15°C.) is equivalent to 4.1855 joules (1 joule = 0.23892 kg.-cal.).

Table 33. Direct and Indirect Calorimetry in Human Subjects

Working..........	66	4682	4676

Source: Atwater, W. O., *Ergebn. d. Physiol.*, **3**, 497, 1904.

There are three principal calorimetric methods: (*a*) direct calorimetry, in which heat eliminated is measured in calorimeters; (*b*) indirect respiratory calorimetry; (*c*) indirect calorimetry by establishing the energy balance. Two of these methods can be combined; the more complete respiratory calorimeters combine all three. Direct and indirect calorimetry give the sam-

[1] Approximately 1 gm. of N in the feces comes from the organism (digestive juices, etc.); the rest is due to undigested food and microorganisms.

results in both the resting and the working subject (Table 33).

The caloric value of foodstuffs is measured by burning them with oxygen in Berthelot's or Mahler's calorimetric bomb submerged in water. The rise in temperature of the water, multiplied by the amount of water, gives the calories; *e.g.*, if there is an increase of 6°C. in the 12 liters of water in which the bomb is submerged, the food burned has set free 72 kg.-cal. The caloric value of a food can also be measured by determining the amount of oxygen needed for the complete combustion of 1 gm. of the food, and converting this into calories.[1]

Direct Calorimetry

The first calorimetric determinations were made by Lavoisier and Laplace. They placed a guinea pig in a closed box surrounded by ice. The heat output of the animal was measured by the amount of water resulting from the ice melted. This heat corresponded to that set free by the combustion of an amount of carbon equivalent to the CO_2 eliminated by the animal. They were thus able to demonstrate for the first time that animal heat has its origin in combustions taking place within the body. Lavoisier and Laplace's calorimeter has only a limited use, because it measures the heat output only at an environmental temperature of 0°C.

[1] Benedict, F. G., and F. L. Fox, *J. Biol. Chem.*, **66**, 783, 1928.

A physiological calorimeter must fulfill the following conditions: (*a*) it should permit exact heat measurements at different temperatures; (*b*) there should be no accumulation of CO_2, nor decrease of oxygen; (*c*) it should be possible to study the influence of food and exercise. Direct calorimetry can be performed by means of (*a*) adiabatic calorimeters; (*b*) gradient calorimeters.
Fig. 180. Diagram of Atwater and Benedict's calorimeter.

An adiabatic calorimeter consists of a closed chamber with walls that do not allow the passage of heat to and from the environment (Fig. 180). Heat radiated by the subject (about three-fourths of the total heat production) is taken up by water circulating in a system of metal pipes within the calorimetric chamber. The increase in the temperature of the water as it passes through the pipes and the total amount of water are measured, thus obtaining the calories radiated by the subject. Water evaporated by the subject is collected in sulfuric acid and weighed; by multiplying the grams of water evaporated by 0.586, the caloric value is obtained. If the temperature of the subject varies in the course of the experiment, the degrees of temperature variation are multiplied by the body weight of the subject and by 0.83 (the specific heat of 1 kg. human body substance, with respect to the specific heat of water, which is 1). For example, if there has been a fall or a rise of temperature of 1° and the subject weighs 70 kg., 58.1 cal. should be subtracted from or added to the total heat loss. Direct calorimetry

is the standard method for measuring the energy converted in the body, but it is costly and complicated, requiring special equipment and trained personnel;[1] for this reason it is not frequently used.

through the lungs and in the urine and feces. Thus the material balance is established, and the energy converted by the subject into heat (when resting) or into heat and work (when working) can be calculated.

Table 34. Intake and Output of Nitrogen, Carbon, and Hydrogen in Man

Condition	Duration of experiment, days	Average daily intake in food, gm.		Average daily output, gm.					Gain or loss
				Feces	Urine	Water	Respiration	Total

* Protein lost by the body: 2.5 gm. (calculated rrom N lost).
† Fat gained by the body: 19.2 gm. (calculated from C retained).
‡ Protein lost by the body: 82.0 gm. (calculated from N lost).
§ Fat lost by the body: 198.3 gm. (calculated from C lost).

Gradient calorimetry consists in measuring thermal output from a source of heat by enclosing it in a shell completely lined with a uniform heat-flow metering layer, while heat lost by ventilation and respiration is measured in heat-exchange meters based on the same principle. Calories conveyed to the heat-measuring gradient layers by radiation, conduction, convection, or evaporation and condensation are measured quantitatively by means of thermojunctions of copper and constantan. The difference in temperature of the different layers, their thickness, and their thermal conductivity are measured and expressed as heat flow in calories per second. Gradient calorimeters are simpler to handle than adiabatic calorimeters and quite as accurate, and the results are obtained very rapidly. They are therefore especially valuable for clinical and physiological work.[2]

INDIRECT CALORIMETRY BY DETERMINATION OF ENERGY BALANCE

Food ingested and oxygen consumption are measured; also the excretion of substances

[1] Among the most complete and exact calorimeters are those of Atwater, Rosa, and Benedict at the Carnegie Institution; of Lusk and Du Bois at the Russell Sage Institute of Pathology in New York; of Lefevre in Paris, etc.

[2] BENZINGER, T. H., and C. KITZINGER, "Direct Calorimetry by Means of the Gradient Principle," Naval Med. Res. Inst. Rep. No. 1, Bethesda, 1949.

In the experiment summarized in Table 34 with the resting subject, there is almost an equilibrium between the intake and output; there is a small loss of nitrogen (0.4 gm.) corresponding to 2.5 gm. protein; a certain amount of fat has been deposited, as is shown by the gain of 13.1 gm. carbon. In the experiment with the fasting subject, considerable loss of protein and fat was observed.

The following calculation is made: The amount of protein, carbohydrate, and fat in the feces is subtracted from that of the food ingested. Nitrogen is multiplied by 6.25 (the protein equivalent). If a subject in the course of 4 days takes in 15.1 gm. of N and eliminates 17.2 gm. (16.2 gm. in the urine, and 0.9 gm. in the feces), the difference, *i.e.*, 2.1 gm., has been lost by the body. The subject consumed 94.4 gm. of protein taken from the food and 13.2 gm. from the organism (a total of 107.5 gm. protein, equivalent to 17.2 gm. N). From the total carbon excreted, protein carbon ($N \times 3.2$) is eliminated; the rest corresponds to carbohydrate and fats. Carbohydrate is considered to be completely consumed; the carbon corresponding to carbohydrate ingested is subtracted from the total and the remainder corresponds to fat. Carbohydrate is obtained by multiplying C by 2.29 (carbohydrates contain 43.5 per cent C). The carbon content of fat is 76 per cent; therefore multiplying C corresponding to fat by 1.31, we have total fat. The caloric value of the protein, carbohydrate, and fat is then calculated.

Caloric value of foodstuffs. In 1842 Joule discovered the mechanical equivalent of heat, and shortly afterward Mayer (1843) and Helmholtz (1847) enunciated the law of conservation of energy, which states that the total energy of the universe is constant but that one form of energy (electrical, mechanical, chemical) can be converted into another. This law of conservation and conversion of energy is also valid in the energetics of animal organisms. This fact was demonstrated by Lavoisier, Pettenkofer and Voit, Rubner, and Benedict and Atwater, and it has been amply confirmed by many others.

Table 35. Calories Obtained from Foodstuffs

Foodstuff	Calories obtained	
	Experimental result	*Approximate practical value*
Fat, 1 gm.	9.3	9
Carbohydrate, 1 gm.	4.1	4
Protein, 1 gm.	4.1	4

Animals convert chemical energy bound in the foodstuffs into heat when resting and into heat and mechanical energy during work. Rubner measured the heat set free by the combustion of different foodstuffs and then determined the heat set free by the organism in the metabolism of those same foodstuffs. He found that fat and carbohydrate gave out the same amount of heat when burned in the calorimeter as in the organism, but that protein gave out less heat in the organism. This is due to the fact that urea and other metabolic waste products of protein metabolism are excreted by the body without being burned and the corresponding calories are lost to the organism, while there is complete combustion of protein in the calorimeter. Thus 1 gm. of protein sets free 5.3 kg.-cal. in the calorimeter and only 4.1 in the organism. On the other hand carbohydrate and fat set free 4.1 and 9.3 kg.-cal. respectively both in the calorimeter and in the organism. These are average values for the three kinds of foodstuffs. There are small differences between the different foodstuffs in each class; thus 1 gm. of starch sets free 4.2 kg.-cal., and 1 gm. of sugar 3.96 kg.-cal. The caloric value of animal proteins is greater than that of vegetable proteins. Taking into account the small loss of heat occurring in the course of digestion and the fact that not all the food ingested is absorbed, in practical dietetics the approximate values given in Table 35 are commonly applied.

At one time it was thought that 1 gm. of carbohydrate, 1 gm. of protein, and 0.45 gm. of fat, which give the same amount of heat, were isodynamic and could be interchanged one for the other. Further studies have considerably restricted the idea of isodynamia. When considering the metabolism of the different foodstuffs it will be seen that there is a minimum requirement of each of them, which cannot be replaced by an equivalent quantity of calories in another type of foodstuff.

Indirect Respiratory Calorimetry

Principle and methods. The amount of energy set free by the oxidation of foodstuffs in the organism can be calculated by measuring the oxygen consumption and the excretion of CO_2 during a certain time (Tables 37 and 38). There are three principal methods for determining respiratory exchanges: (*a*) confinement in a closed chamber; (*b*) the open-circuit method; (*c*) the closed-circuit method. In all these methods the whole animal can be placed within a respiratory chamber or the respiratory tract alone can be connected with a device for measuring its gaseous exchanges. In the latter case a mouthpiece, nasal catheter, or mask is used, taking good care to prevent leakage to or from the outside air. A system of valves which offer no resistance to breathing, but are perfectly competent, assures the circulation of air in one direction. The time over which the observation is made should be accurately measured, because the results are then expressed in terms of 1 hr. or 24 hr.

Confinement. Lavoisier used this method in his pioneer experiments in calorimetry. Its uses are limited to small animals and to observations of very short duration, because the decrease in oxygen and the accumulation of CO_2 soon disturb the normal functions of the animal.

Closed circuit. This method introduced by Regnault and Reiset in 1849 has since been frequently applied in different apparatus for metabolic determinations. The subject breathes air from and into a closed space; CO_2 and water are removed from the expired air by passing it through appropriate absorbents, and oxygen is added to the inspired air to replace what is absorbed by the organism. The method was ap-

plied in man in the Atwater-Rosa-Benedict respiratory calorimeter, for direct and indirect respiratory calorimetry. This apparatus permits the simultaneous measurement of heat production by both methods (Table 33). Air is made to circulate through the calorimetric chamber by means of a pump (Fig. 180). On leaving the chamber it passes through a flask containing sulfuric acid, which absorbs the water; then through a second flask containing soda lime, for the absorption of CO_2; then through a third flask with H_2SO_4, which absorbs water produced in the reaction between CO_2 and soda lime. The increase in weight of the first flask gives the subject's output of water; the increase in weight of the second and third flasks gives the CO_2 output. Oxygen absorbed by the subject is replaced from a tank; weight lost by this tank gives the oxygen consumption. The calorimetric chamber is large enough to allow the subject to live in it for several days; is furnished with a bed, a table, a telephone for outside communication, and a bicycle ergometer which accurately measures energy spent in work. This calorimeter has been used to give a precise demonstration that in man the energy output at rest (in the form of heat) or when working (heat and mechanical energy) is equivalent to the energy set free by the combustion of foodstuffs in the organism (Table 33). Direct and indirect calorimetry give equal results if performed for a sufficiently long period; during short periods there are sometimes certain differences. Thus during shivering and when the body temperature rises, the oxygen

FIG. 181. Diagram of Benedict-Roth recording spirometer.

consumption is greater than the output of heat. This is due to the retention of heat by the organism while the body temperature rises.

In medical practice the only method widely used is indirect respiratory calorimetry, because it is accurate and simple and does not require costly apparatus. A recording spirometer such as the Benedict-Roth model is used (Fig. 181). The subject breathes in and out of the spirometer, which is filled with oxygen. A set of valves directs the expired air into a receptacle with soda lime where CO_2 is absorbed. At each respiratory movement the bell of the spirometer rises and falls, tracing a continuously descending line as the subject takes up oxygen. The records (Fig. 182) are usually taken over a period of 6 min. and the result is calculated for 1 hr.

FIG. 182. A satisfactory record of oxygen consumption.

Knipping's apparatus measures oxygen consumption and CO_2 elimination. Expired air is breathed into a spirometer, and a pump then passes it into a flask containing KOH to absorb the CO_2, whence it is breathed in by the subject. The fall of the bell of the spirometer gives the oxygen consumption; the spirometer can be refilled with O_2 if a more prolonged observation is desired. The apparatus is then closed, and H_2SO_4 is poured into the flask containing KOH; CO_2 breathed out by the subject and absorbed by KOH is set free into the spirometer, the bell rises and the volume of CO_2 is thus measured.

Open circuit. In this method air or oxygen is breathed from the atmosphere, or from a tank; the expired air is measured and released into the atmosphere.

Haldane's apparatus (Fig. 183) for small animals (mice, rats, guinea pigs) gives excellent results.[1] The animal is placed in a small chamber, and air is made to circulate through the whole system by means of an aspirator or pump. Incoming air passes through soda lime and H_2SO_4, which absorb CO_2 and water. Outgoing air passes through sulfuric acid, where it is dried; then through soda lime, which absorbs CO_2; and finally through H_2SO_4, which absorbs water set free in the combination of CO_2 with soda lime. The flasks on the outgoing side are weighed at the beginning and end of the experiment. The increase in weight in the first two flasks containing H_2SO_4 gives the elimination of water; the
FIG. 183. Haldane-Pembrey respiration apparatus for small animals.

[1] HALDANE, J. S., *J. Physiol.*, 13, 419, 1892.

increase in weight in the other two flasks (soda lime and H_2SO_4) gives the CO_2 eliminated by the animal. Oxygen consumption is obtained indirectly by the following calculation: During the experiment only CO_2 and water are produced, and only oxygen is absorbed. The chamber with the animal is weighed at the beginning and end of the experiment. The difference is subtracted from the weight of CO_2 and water eliminated; the result corresponds to the weight of oxygen absorbed.

In man a Douglas bag (Fig. 184) strapped on the back can be used for collecting the expired air from subjects in many different physiologic conditions. A three-way stopcock (*B*) permits the expired air to pass into the bag or into the atmosphere. The subject breathes through a mouthpiece (1) into a set of perfectly competent valves (2) which direct the expired air into the rubber pipe going to the bag. The stopcock (3) is at first turned so that the expired air is blown out into the air; at a given moment it is turned so that the expired air goes into the bag during an accurately measured time. The bag is then closed by turning the stopcock and taken to the laboratory. The expired air in the bag is measured by passing it through a gas meter, and a sample is drawn into a Haldane buret.
Fig. 184. Douglas bag for determining respiratory exchanges in man. Below: 1, mouthpiece; 2, inspiratory and expiratory valves; 3, stopcock for communicating the bag with the atmosphere or with the mouthpiece. Above: the bag is connected by a rubber tube with a gas meter; a sample of expired air is collected in the buret filled with mercury.

Instead of a Douglas bag, an accurately calibrated and balanced Tissot spirometer[1] can be used (Fig. 185). The subject breathes through a mask or mouthpiece and the expired air is directed by a set of valves into the spirometer, where it is measured. A sample is collected, and CO_2 and oxygen content are determined.

In the Haldane buret (Fig. 186) a small amount of expired air is accurately measured. CO_2 is absorbed by passing the air several times through a flask con-

[1] Boothby's, Bailey's, and other models can also be used.

taining KOH. The sample is again measured and the decrease in volume corresponds to the CO_2. Then the air is passed into a flask with alkaline pyrogallate, where the oxygen is absorbed. The sample is measured and the decrease in volume corresponds to the O_2. The composition of expired air is thus known, and
FIG. 185. Diagram of Tissot's spirometer. 1, mouthpiece; 2, nasal catheter. Expired air is sent through a valve into the bell of the spirometer, which is accurately calibrated and well balanced so that it does not offer any resistance to expiration, nor does it compress the gas collected.

as the composition of external air is constant, O_2 absorbed and CO_2 eliminated by the organism are easily calculated.

The Tissot-Boothby method, using the Haldane buret for the determination of respiratory metabolism, is very accurate but requires experience in gas analysis. The Benedict-Roth method is much simpler and is therefore more commonly used in medical practice. In both these methods care should be taken that the subject be physically and mentally at ease and his breathing regular. For this it is important that the mask or mouthpiece used should be comfortable and the valves and bell of the gasometer should not offer any resistance to breathing. The great drawback in these methods is the short time during which the sample is collected; as the results of a few minutes are expressed in terms of 1 hr., any transitory disturbance in respiratory metabolism or any error committed is multiplied several times. Far more reliable results are obtained when the observation lasts several hours or days, as when respiratory calorimeters are used. Working with two Tissot spirometers, it is possible to prolong the observation for a fairly long time, switching from one to the other and taking samples of expired air alternately from each gasometer.

Respiratory quotient.[1] The ratio of the volume of CO_2 eliminated to the volume of O_2 absorbed is known as the respiratory quotient (RQ). The volumes of the gases are considered
FIG. 186. Haldane's apparatus for gas analysis. *A*, buret for measuring the sample of air or gas to be analyzed; *F*, pipet containing KOH for absorption of CO_2; *H*, pipet containing potassium pyrogallate for absorption of oxygen; *R*, mercury reservoir for shifting the gas.

because according to Avogadro's law one molecule of O_2 has the same volume as one molecule of CO_2.

If foodstuffs are burned in oxygen *in vitro*, the RQ varies according to the foodstuff; therefore

[1] RICHARDSON, H. B., *Physiol. Rev.*, **9**, 61, 1929.

the same variations must occur when they are burned in the organism.

The general formula of carbohydrates may be expressed as $C_n(H_2O)_n$; therefore in the course of combustion all the oxygen combines with C and forms CO_2. For example, in the combustion of glucose,

Table 36. Composition of Meat and Its Excreta

	C, *gm.*	*H*, *gm.*	*O*, *gm.*	*N*, *gm.*	*S*, *gm.*
Amount contained in 100 gm. meat	52.38	7.27	22.68	16.65	1.02
Residue eliminated in urine and feces	10.88	2.87	14.99	16.65	1.02
Balance used in combustion	41.50	4.40	7.69		

$$C_6H_{12}O_6 + 6O_2 = 6CO_2 + 6H_2O$$
The RQ will be equal to 1, because

$$RQ = \frac{6 \text{ vol. } CO_2}{6 \text{ vol. } O_2} = 1$$

In the combustion of fats O_2 is used up to oxidize not only carbon but also hydrogen. The RQ is therefore less than 1; for the fats in foodstuffs it is approximately 0.7. For example, in the combustion of tripalmitin,

$$2(C_{51}H_{98}O_6) + 145O_2 = 102CO_2 + 98H_2O$$

$$RQ = \frac{102 \text{ vol. } CO_2}{145 \text{ vol. } O_2} = 0.703$$
In the case of protein it is necessary to consider that some of the end products are eliminated in the urine and feces without being completely oxidized. C and H in the rest of the molecule are oxidized and eliminated as water and CO_2 (Table 36); for this purpose 138.18 gm. of O_2 is absorbed and 152.17 gm. of CO_2 is eliminated. As 1 gm. of O_2 = 0.6998 liters, and 1 gm. of CO_2 = 0.5094 liters, the following RQ results:

$$RQ = \frac{77.52 \text{ liters } CO_2}{96.7 \text{ liters } O_2} = 0.802$$

When carbohydrate is converted into fat, CO_2 is set free without the absorption of O_2; therefore the RQ is more than 1. If, on the contrary, fat is converted into carbohydrate, the consumption of O_2 for this purpose, without the corresponding elimination of CO_2, would cause the RQ to fall to approximately 0.3.

The RQ indicates which substances are being burned in the organism (Table 37). It must be remembered, however, that the figures given refer to each kind of foodstuff separately and that the body never burns exclusively one kind of substance, but the three principal kinds simultaneously; therefore the RQ is the result of many different chemical processes. Even when an excess of carbohydrate (*e.g.*, glucose) is given by mouth or in intravenous injection, the RQ rises only to 0.87; therefore other substances beside sugar are being burned.

When sugar is given to a patient with a severe diabetes, the RQ, which in these cases is 0.7, does not rise. It has been generally accepted that this means sugar cannot be burned in this condition, but this is not the only possible interpretation,[1] because an RQ of 0.7 may result from two processes that occur simultaneously and have opposite effects on the RQ; *e.g.*, sugar may be burned giving an RQ of 1, and at the same time carbohydrate may be converted into fat (there is as yet no final proof that this occurs), giving an RQ of 0.3.

In several conditions there is an apparent

[1] There is definite proof that the tissues of diabetics burn sugar, but at a lower rate than normal tissues.

increase in the RQ due not to changes in the oxidation processes taking place in the body, but to the elimination of CO_2 stored in the alkali reserve. There are two main conditions in which this occurs: (*a*) when hyperventilation eliminates CO_2 in the alveolar air and the blood, without there being an increased formation of CO_2; (*b*) when an excess of acid enters into the blood and displaces CO_2 from bicarbonates; *e.g.*, lactic acid produced by muscular contraction, or ketonic bodies in diabetic ketosis and in acidosis due to the ingestion of ammonium chloride or calcium chloride.

Table 38. Caloric Value of Oxygen in the Body

RQ	*Calories per liter of O_2 consumed*	*Percentage of total heat produced by carbohydrate*	*Percentage of total heat produced by fat*
0.77	4.686	0	100.0
0.75	4.739	15.6	84.4
0.80	4.801	33.4	66.6
0.85	4.862	50.7	49.3
0.90	4.924	67.5	32.5
0.95	4.985	84.0	16.0
1.00	5.047	100.0	0

Source: Zunz and Schumburg, modified by Lusk, and later corrected by Cathcart and Cuthbertson (*J. Physiol.*, **72**, 349, 1931). According to E. P. Poulton (*Proc. Roy. Soc. Med.*, **26**, 1591, 1933), these figures are not completely accurate.

Conversely, an apparent decrease of the RQ can be observed when there is retention of CO_2 without any change in the oxidation processes of the body. Thus CO_2 is retained in hypoventilation and in alkalosis provoked by excess elimination of acids (repeated vomiting, etc.) or by excess ingestion of alkali.

The caloric value of oxygen. Three data are necessary for the calculation of respiratory metabolism: (*a*) the amount of O_2 absorbed, in liters; (*b*) the duration of the experiment; (*c*) the caloric value of 1 liter of oxygen.

The amount of heat produced by 1 liter of O_2 varies according to the substance oxidized (Table 38). One liter of oxygen oxidizing carbohydrate sets free 5.047 kg.-cal., while it gives only 4.686 cal. when fat is oxidized.

The RQ must therefore be known to obtain accurately the caloric value of the oxygen absorbed (Table 38). If the RQ is not known, as is the case when using the Benedict-Roth spirometer, an average caloric value of 4.825 kg.-cal., corresponding to an RQ of 0.82,[1] is attributed to each liter of O_2. If the subject's RQ is above or below 0.82, an error will be committed, but it is never greater than ± 7 per cent.

If, instead of measuring the O_2 absorbed, only the CO_2 eliminated is determined and a caloric value corresponding to an RQ intermediate between 0.7 and 1 is attributed to the CO_2, the maximum possible error will be ± 15 per cent. Moreover, as was explained previously, the elimination of CO_2 is subject to variations that do not correspond to changes in the oxidizations taking place in the body. For these reasons respiratory calorimetry is not based on CO_2 determinations alone, whenever the O_2 consumption can be measured.

In more precise experiments the nonprotein RQ is determined. For example, a subject eliminates 13.5 liters of CO_2, absorbs 16 liters of O_2, and eliminates 0.5 gm. of N in the urine, per hr. For each gram of N produced in the combustion of proteins, there is an output of 4.76 liters of CO_2 and 5.94 liters of oxygen are absorbed. Therefore, in the example given, $0.5 \times 4.76 = 2.38$ liters of CO_2 and $0.5 \times 5.94 = 2.97$ liters of O_2 correspond to protein metabolism; $13.5 - 2.38 = 11.12$ liters of CO_2 and $16 - 2.97 = 13.03$ liters of O_2 correspond to carbohydrate and fat burned. Therefore,

$$\text{Nonprotein RQ} = \frac{11.12 \text{ liters } CO_2}{13.03 \text{ liters } O_2} = 0.85$$

The caloric value of O_2 at this RQ is 4.862; therefore the heat output per hour is $13.03 \times 4.682 = 63.3$ kg.-cal., 50.7 per cent from the oxidation of carbohydrate and 49.3 per cent from that of fat. Protein metabolism gives rise to $2.97 \times 4.485 = 13.3$ kg.-cal. This figure can also be obtained by multiplying the amount of nitrogen excreted by its caloric equivalent, *i.e.*, $0.5 \times 26.51 = 13.3$ kg.-cal. Total heat production per hour in the subject taken as an example is $63.3 + 13.3 = 76.6$ kg.-cal.; 42 per cent of this total is obtained from carbohydrate, 41 per cent from fat, and 17 per cent from protein. A less precise but fairly accurate calculation can be made by considering the RQ as the result of carbohydrate and fat combustion, without taking into account the protein metabolized. Thus nitrogen determinations are not necessary and no considerable error is made.

[1] This is the RQ most commonly observed in fasting subjects, the condition in which basal metabolism is determined.

BASAL METABOLISM

Significance. The total energy converted by the human organism can be differentiated into two parts:

1. A constant or basal metabolism; *i.e.*, the minimum energy necessary for the maintenance of normal function.
2. An additional variable quota of energy expended in work, in the maintenance of the body temperature, and in the postabsorptive condition (a short period following the absorption of food).

The true minimum metabolism is not easy to determine, because what is usually called "basal metabolism" diminishes during sleep, in poorly fed subjects and in sedentary ones. Therefore it is more convenient to define basal metabolism as the energy output observed under certain special conditions, known as "basal conditions," in which exercise, outside temperature, and the recent absorption of food have no influence on energy exchanges.

There are three fundamental basal conditions: (*a*) the subject must be resting comfortably, relaxed, without moving, for ½ to 1 hr. before the determination is made, and must not have performed any violent exercise recently; (*b*) outside temperature must be approximately 20°C. (16 to 25°C.); (*c*) the subject must not have ingested any food for 12 to 16 hr. (postabsorptive period) before the determination. Krogh recommends that no protein be taken on the night before and that the test be performed between 8:00 and 9:00 A.M. The subject should not be in a condition of emotional excitement, but should be quiet, his pulse and breathing regular, and his body temperature normal.

The term "basal metabolism" or "basal metabolic rate" has come into common use, but "standard metabolism" proposed by Krogh would be more appropriate.[1] It is the sum of the metabolic activity of the different organs, *i.e.*, of the heart (4 to 5 per cent), kidneys (5 to 7 per cent), liver, digestive tract, contraction of the respiratory muscles, maintenance of muscle tone, etc. This activity is controlled by the nervous system and the endocrine glands. It is usual to express the basal metabolic rate in calories per square meter per hour.

Basal metabolic rate and body mass. Basal metabolic rate per kilogram of body weight is greater in small animals than in large. If the basal metabolic rate is calculated per square meter of body surface, however, approximately the same figures are found for large and small animals. This fact led to the statement that the basal metabolic rate is proportional to the area of the body surface, known as the "law of surface area," put forward by Rubner (1883) and Richet (1889). This does not mean that heat production is dependent on the heat lost through the skin, because if this were so heat production would cease when the outside temperature was equal to the body temperature, and it does not cease even when the temperature of the environment is higher than the body temperature (Du Bois).

Meeh determined the surface area using the following formula:

$$S = KW^{0.66}$$

where W is the body weight in kilograms and K is a constant which varies for each species but which is approximately equal to 10. Du Bois and Du Bois studied the body surface of man by applying paper patterns on the skin and measuring the total area. They arrived thus at the following empiric, but more accurate, formula:

$$\text{Surface (in sq. cm.)} = \text{Weight (in kg.)}^{0.425} \times \text{Height (in cm.)}^{0.725} \times 71.84$$

By the application of this formula, charts have been made for calculating the body surface of an individual (Figs. 187 and 188) from his body weight and height. These charts are in common use in medical practice.

The "law of surface area" is not strictly accurate because heat production per square meter of body surface is somewhat greater in large animals than in small ones (Benedict); it also varies with the climate (Galvao). Certain authors have discarded this "law" and maintain that heat production is dependent on the active protoplasmic mass (Benedict), on the physiologic (not the physical) weight (Brody), or on a principle of biological similarity (Kayser)—terms which are not easily defined.

The basal metabolism of many homoiothermic

[1] Other terms have been used, such as "fundamental metabolism" (Grundumsatz, Magnus Levy), "postabsorptive metabolism" (Benedict), "minimum physiological energy" (Lefevre), "maintenance metabolism," etc.
FIG. 187. Du Bois's chart for determining surface area of man from weight and height.
FIG. 188. Boothby and Sandiford's nomogram for determining surface area of man. The point on the scale on the left corresponding to the subject's height in centimeters is joined by a straight line to the point on the scale on the right corresponding to his weight in kilograms. The point where this line crosses the scale in the middle gives the surface area in square meters.

species is proportional to a power of the body weight. According to Brody this power is 0.73, and according to Kleiber it is 0.75. Kleiber (1947) has proposed the following formula for man: BMR = 70 kg.-cal. $\times W^{0.75}$ per day, or BMR = 3 kg.-cal. $\times W^{3/4}$ per hr. Günther[1] gives a similar formula: $\frac{\text{kg.-cal./hr.}}{W^{0.734}} = 3$ (men) or 2.85 (women).

In the city of São Paulo (Brazil) on the Southern tropic, Galvao (1951) found the following figures for men and women of different build:

Lean: $\text{BMR} = \frac{\text{kg.-cal./hr.}}{W^{0.83}} = 2.038$ (men), 2.012 (women)

Medium: $\text{BMR} = \frac{\text{kg.-cal./hr.}}{W^{0.78}} = 2.334$ (men), 2.168 (women)

Obese: $\text{BMR} = \frac{\text{kg.-cal./hr.}}{W^{0.71}} = 3.158$ (men), 2.919 (women)

According to Galvao, in cold and temperate climates, heat production and loss are apparently related to the body surface, but in tropical climates they are related to the metabolically active part of the body weight.

The metabolism of poikilothermic vertebrates is also related to a power of the body weight; at 20°C., BMR = $1.78W^{0.728}$ (Kayser, 1951). Many other anatomical and functional characteristics of mammals are related to a power of the body weight, as if they were conditioned by similar regulatory mechanisms or equilibriums (Adolph, 1949).

The expression of the results. The basal metabolic rate is usually given in kilogram-calories per square meter per hour. Average values in man have been established by several workers (Table 39); 68 per cent of the subjects

[1] GÜNTHER, B., *Bol. Soc. biol. Concepción, Chile,* **18,** 45, 1944; *Medicina, Buenos Aires,* **6,** 261, 1946.

the mean; 90 per cent are within ±15 per cent of the mean, and 95 per cent within ±18 per cent (Fig. 189). In medical practice, values within ±15 per cent of mean are considered normal, and those ±20 per cent are considered as almost certainly due to some abnormal condition. The BMR is usually expressed as the percentage deviation from the normal corresponding to the age and sex of the subject. For example, a man twenty-five years old has an output of 45 kg.-cal. per sq. m. per hr., the mean for that age and sex being 40 kg.-cal. per sq. m. per hr. The BMR will be expressed as follows:

$$\frac{(45 - 40)100}{40} = +12.5 \text{ per cent}$$
FIG. 189. Normal basal metabolism. Frequency curve of normal values observed in 7,117 women at the Mayo Clinic. The average found in this series was +1.94 with a standard deviation of 9.7. (*Boothby, W. M., J. Berkson, and W. A. Plummer, Tr. Am. A. Study of Goiter, 1937.*)

It is advisable to repeat the determination several times, to arrive at the BMR corresponding to a given subject, especially if abnormal results are obtained in the first observation. In this way mistakes due to emotional disturbance or infringement of one of the basal conditions are avoided.

FACTORS THAT MODIFY BASAL METABOLISM

The basal metabolic rate varies with age, sex, size, the nutritional condition (overfeeding, malnutrition), athletic training, sleep, climate, altitude, and body temperature. It is constant in the same subject on different days.

Age. The newborn child has a low BMR (26 kg.-cal. per sq.m. per hr.). It rises gradually with age up to a maximum when the child is between three and six years old; then it falls until there is a slight rise at puberty, followed by a gradual decrease up to about twenty years of age. Then it falls at a slower rate as age advances (Table 39, Fig. 190).

Sex. The BMR is approximately 7 per cent higher in the male than in the female of the same age.

Malnutrition. This condition is perhaps the most frequent cause of low BMR in otherwise normal subjects.

Training. Athletes in training may have a BMR 3 to 6 per cent above the average, but this depends in great part on the capacity of the subject to relax his muscles while the determination is being made. Subjects with sedentary habits may have a low BMR.
FIG. 190. Influence of age and sex on basal metabolic rate. Abscissa, age in years; ordinate, BMR in kilogram-calories per square meter per hour.

Sleep. During deep sleep the BMR falls from 6 to 13 per cent.

Climate and race. Ozorio de Almeida[1] found a BMR on an average 20 per cent lower in Rio de Janeiro than the normal figures for countries with a temperate climate, and he maintained that living in a tropical climate causes a decrease in BMR. Several observers have found low basal metabolic rates in subjects living in hot climates in Australia, Brazil, India, China, and the southern United States, but not as low as those reported by Ozorio de Almeida (Castro, Oliveira, Orsini, Galvao).[2] Normal basal metabolic rates have been found in Argentina, Cuba (Coro), Peru (Hurtado), and Mexico (Roca). Racial differences apparently also have an influence on the BMR; thus the Mayas of Yucatan (Benedict) and the Araucarian Mapuche Indians of southern Chile (Pi-Suñer) have a slightly higher average BMR than whites living in a moderate climate. It is sometimes difficult to distinguish between the effects of climate (heat and humidity), race, nutritional condition, work, etc.

Altitude. There is little change in the BMR unless the oxygen partial pressure falls to nearly half the oxygen pressure at sea level; with lower oxygen tensions, the BMR increases. In severe anoxia the BMR falls gradually.

Psychic influences. Mental work, even when it is intense, does not modify the BMR significantly; sometimes there is a slight rise of not more than 4 per cent. In emotional states there is a rise of 5 to 20 per cent due to increase in muscular tone, tachycardia, and increased respiratory frequency.

The endocrine glands. *Thyroid.* The thyroid gland plays an important part in the control of oxidations in the organism, therefore of the BMR. Thyroid secretion has a continuous stimulating effect on basal metabolism. Thyroid insufficiency causes a decrease in the BMR of 25 to 40 per cent (Fig. 191), but a rate 15 to 20 per cent below the average is not usually due to hypothyroidism but to other causes (Boothby). Thyroid given by mouth or thyroxin injections raise the BMR of hypothyroid patients. Hyperthyroidism due to over-activity of the thyroid or provoked experimentally by excess thyroid administration causes the BMR to rise. Thyroidectomy in hyperthyroid patients produces a fall to normal or below normal. BMR determinations are of great importance for the diagnosis of the level of thyroid function and in the control of treatment of hyperthyroidism and hypothyroidism.

Hypophysis. The anterior lobe of the hypophysis stimulates the development of thyroid function and maintains its normal level. Anterior hypophyseal lobe insufficiency causes hypothyroidism and therefore a fall in the BMR. Hyperfunction of the anterior hypophyseal lobe, on the contrary, causes hyperthyroidism and a rise in the BMR.

Adrenals. In uncompensated, but not in compensated, adrenal insufficiency there is a low BMR. A sudden discharge of adrenaline from the adrenal medulla causes a rise of the BMR during several minutes, or at most a few hours.

Gonads. The difference in the BMR in the sexes has already been mentioned. Castration diminishes basal metabolism in 20 to 25 per cent of human subjects. Menstruation has little or no effect; frequently there is a slight premenstrual rise in temperature and in BMR and a decrease during the flow.

Pregnancy. During the first half of pregnancy there is no change in the BMR, but in the latter half there is a rise of about 8 per cent at the fifth month and 14 to 33 per cent during the last

[1] OZORIO DE ALMEIDA, A., *J. de physiol. et de path. gén.*, **18**, 713, 1919; **18**, 958, 1920.

[2] MOURA CAMPOS, F., Atti VII Conv. Volta, Roma, 1937, p. 68; *Folha med.*, **20**, 73, 1939.

2 months. The total basal metabolism is equal to the BMR of the mother plus that of the fetus. There is no proof that maternal metabolism is stimulated by pregnancy.

Other factors. Occupation, race, diet, work performed or emotional stress on the day before the determination, the effect of novelty in the first determination, and the season of the year are factors that sometimes have a slight influence on the BMR.

Disease. The BMR is increased in hyperthyroidism (25 to 80 per cent), fever (13 per cent per degree centigrade), dyspnea (25 to 60 per cent), leukemia (20 to 80 per cent), polycythemia (10 to 40 per cent), and some cases of severe anemia. It is low in hypothyroidism (30 to 40 per cent), hypophyseal insufficiency, adrenal insufficiency (Addison's disease), and malnutrition.

Drugs. The following drugs increase the BMR: adrenaline, thyroid and thyroxine, caffeine, benzedrine, dinitrophenol and dinitrocresol, etc. The BMR is depressed by anesthetics and by depression of the central nervous system and muscle tone.

Fig. 191. Basal metabolic rate in thyroid disease. From left to right: spontaneous myxedema; normal distribution (smooth curve); adenomatous goiter, with and without clinical hyperthyroidism; exophthalmic goiter. Ordinate, percentage frequency for each group. Abscissa, metabolic rate percentage deviation from normal (= 0). Almost all cases of myxedema are below normal, and those of exophthalmic goiter are above normal; cases with thyroid adenoma form a heterogeneous group. (*Boothby, W. M., J. Berkson, and W. A. Plummer, Ann. Int. Med., vol. 11, p. 1014, 1937.*)

The Effect of Exercise, Temperature, and Food on Total Metabolism

The simple act of standing up and performing a few movements causes heat production to rise by 25 to 50 per cent; in the course of normal activity the metabolic rate is frequently twice the basal level, and in violent exercise it can be 10 to 16 times the basal rate (see Chap. 47).

External temperature has a marked influence on heat production. A minimum BMR is observed when the subject is at a temperature of 18 to 30°C. (20 to 25°C.). Environmental temperature above 30°C. causes a slight rise in the metabolic rate and in body temperature. When the temperature falls below 15°C. muscular tone increases, there may be shivering, and heat production rises (see Chap. 48). In fever there is a rise in heat production of approximately 13 per cent of the BMR for each degree centigrade increase (Du Bois).

Metabolism is stimulated by the absorption of food, especially of protein. This is known as the specific dynamic action of foodstuffs (see Chap. 43, Protein Metabolism).

CHAPTER 41

Carbohydrate Metabolism

Absorption. The process of digestion in man splits carbohydrates into monosaccharides, and they are absorbed as such, mainly in the form of the hexoses: glucose, fructose, and galactose. Absorption takes place principally in the small intestine, and only in small amounts in the colon. Insignificant quantities of carbohydrate are absorbed in the stomach, except when concentrated solutions are given for experimental purposes. Sugars pass through the intestinal mucosa exclusively in a one-way direction, from the lumen of the intestine to the blood stream. The velocity of absorption varies from one sugar to another. If the conventional value of 100 is given to the amount of glucose absorbed in unit time, the following values are found in the rat for the absorption of other sugars: galactose, 110; fructose, 43; mannose, 19; xylose, 15; arabinose, 9 (Cori). These figures show that glucose and galactose are absorbed at a much higher rate than any of the others. This selective absorption is impaired if the animals are kept at low temperatures (from 0 to 20°C.), in some endocrine insufficiencies (adrenal, thyroid, hypophysis), and in cases of intoxication by certain drugs. In these cases all sugars are absorbed at the same rate. The mechanism responsible for selective absorption has not yet been clearly demonstrated; nevertheless many facts indicate that it is due to phosphorylation of glucose and galactose, according to Verzár's hypothesis, while other sugars are absorbed by simple diffusion. Monoiodoacetic acid and phlorhizin inhibit phosphorylation, thus suppressing selective absorption.

The thyroid plays a definite part in the selective absorption of glucose and especially of galactose. These sugars are absorbed at a much slower rate in hypothyroidism and at a higher rate in hyperthyroidism. In adrenal insufficiency the selective absorption of glucose is disturbed. The normal condition is restored by treatment with corticoadrenal hormones or simply by giving sodium chloride.

Distribution in the organism. Glucose and glycogen are the principal carbohydrates in the human body; milk contains lactose. Carbohydrates are also found combined with fats (galactosides or cerebrosides), proteins (glycoproteins), or phosphoric acid (hexosephosphates and triosephosphates). Desoxyribose and ribose are found in nucleic acids and their derivatives, and in certain coenzymes. Phosphoric esters of glucose and fructose are of importance in the intermediate metabolism of carbohydrates.

Glycogen. This carbohydrate, discovered by Claude Bernard, is a polysaccharide corresponding to the formula $(C_6H_{10}O_5)^x$. It is a white powder, giving opalescent colloidal solutions, and taking on a dark red color in the presence of iodine. It is hydrolyzed by acids and amylolytic enzymes, giving glucose as a final product.

Glycogen[1] is found in many tissues, and there are large quantities in the liver, muscle, and heart. Glycogen and glucose concentrations vary in the different tissues (Table 40).

Although the liver has a higher glycogen concentration than muscle, the total amount of liver glycogen (75 to 200 gm.) is usually less than that of muscle glycogen (180 to 300 gm.), because the liver makes up only 3.3 per cent of the body weight, while the muscles are almost 50 per cent. Chemical transformation of glycogen varies considerably

[1] Glycogen is usually isolated and estimated by Pflüger's method or a modification of this method. The tissue is boiled for 2 to 4 hr. in 60 per cent KOH, which dissolves protein but does not attack glycogen; alcohol up to 70 per cent is then added to precipitate glycogen, which is washed and hydrolyzed with 2.2 per cent HCl for 2 hr. Glucose thus formed is then estimated.

in the different tissues, because of the different chemical systems responsible for its formation and destruction.[1] There are remarkable differences between liver and muscle glycogen (Table 41). Every day 69 per cent of the glycogen in the liver is renewed (Stetten). The process of

glycogen formation is known as glycogenesis, and its disintegration is called glycogenolysis.

Hexosamines. Glucoseamine and galactoseamine are found in the body; in the former, one OH is replaced by an amine (NH_2). There are also uronic acids, the most common one being glucuronic acid; its formula is the same as that of glucose, but a carboxyl group substitutes for the primary alcohol. Condroitinsulfuric acid is an important constituent of cartilage and tendons; it is a polymer of glucuronic acid and glucosamine with sulfate and acetyl groups.

Hyaluronic acid, found in the umbilical cord, the synovial fluid, the vitreous body, and the skin, is made up of glucuronic acid and acetylglucosamine. An enzyme, hyaluronidase, hydrolyzes hyaluronic acid and diminishes its viscosity. If hyaluronidase is added to a fluid injected subcutaneously, this diffuses rapidly in the dermis (spreading factor). Certain anaerobic bacteria and snake venoms spread quickly because they contain this enzyme. The testes have a large amount of hyaluronidase, which is excreted in the seminal fluid and aids the penetration of the spermatozoon into the ovum by

dissolving the hyaluronic acid cuticle which surrounds it.

Origin and fate of carbohydrate in the organism. Carbohydrate in the body arises (*a*) from carbohydrate in foodstuffs, and (*b*) from substances other than carbohydrate (glyconeogenesis) such as certain amino acids and in smaller amounts from fatty acids.

Glucose is absorbed from the intestine into the blood stream; it then passes by diffusion through the capillary walls into the tissue fluids (Fig. 192). Glucose then follows one of three main paths: (*a*) conversion into glycogen; (*b*) conversion into fat; (*c*) oxidation into CO_2 and H_2O, which are eliminated.[1]

Up to quite recently it was believed that glucose absorbed from the intestine was mainly converted into glycogen. Experiments performed by feeding rats with "labeled" glucose (*i.e.*, glucose containing deuterium, or "heavy" hydrogen, in its molecule) have shown that only 3 per cent is deposited as glycogen and 30 per cent is converted into fat.[2]

INTERMEDIARY CARBOHYDRATE METABOLISM

The synthesis of glycogen and the oxidation of glucose into CO_2 and H_2O are performed only after a process of esterification with phosphate. The different reactions are illustrated on

[1] Thus in severe diabetes glycogen diminishes considerably in the liver and to some extent in muscle; on the contrary it increases in the heart, leukocytes, and kidneys.

[1] Part of the CO_2 can transitorily form part of intermediate metabolic products.

[2] STETTEN, DE W., *J. A. M. A.*, **132**, 373, 1946; *Proc. Am. Diabetes A.*, **7**, 67, 1948.

page 403. All these reactions can be considered as reversible (the arrows have been drawn in only one direction in order to simplify the diagram).

Free glucose is not used until it is phosphorylated by an enzyme, hexokinase, which catalyzes the following reaction:

Glucose + ATP → Glucose-6-phosphate + ADP
ATP signifies adenosinetriphosphate, and ADP adenosinediphosphate.

In stage 1, phosphate is transferred from ATP to glucose, which must be phosphorylated in order to be utilized. In stage 2, phosphis ate transferred from position 6 in glucose-1-6-diphosphate to position 1 of glucose-6-phosphate,[1] with the formation of glucose-1-phosphate and regeneration of glucose-1-6-diphosphate; which has therefore acted catalytically. In stage 3, phosphorylase converts glucose-1-phosphate into glycogen and releases inorganic phosphate.

Adenosinetriphosphate.

In the tissues adenosinemonophosphate is also found. These adenosinephosphates act as phosphate carriers—donors or acceptors, according to the reaction. Further on, processes will be described in which ADP accepts phosphate and is converted into ATP.

After glucose-6-phosphate has been formed by the action of hexokinase, several metabolic paths are opened:

Glucose-6-phosphate:
- (*a*) Glucose-1-phosphate ⇌ glycogen
- (*b*) Fructose-6-phosphate ⇌ lactic acid or $CO_2 + H_2O$
- (*c*) Phosphogluconate followed by oxidation
- (*d*) Glucose + phosphate (especially in the liver)
It should be noted that other hexoses such as fructose, mannose, and galactose are also phosphorylated by ATP.

Glycogen synthesis and breakdown. The conversion of glucose into glycogen takes place in three stages:

1. Glucose + ATP → glucose-6-phosphate + ADP (*hexokinase*)
2. Glucose-6-phosphate → glucose-1-phosphate (*phosphoglucomutase*, glucose-1-6-diphosphate acts as coenzyme)
3. Glucose-1-phosphate → glycogen + phosphate (*phosphorylase*)

Conversion of glycogen into glucose follows the same path in the opposite direction. Glycogen, as a result of the action of phosphorylase, gives glucose-1-phosphate, which is converted by phosphoglucomutase into glucose-6-phosphate, and finally free glucose and phosphate are formed.

Glycogen is made up of many units of glucose, united like the links of a chain. An oxygen atom unites the first carbon of one glucose molecule to the fourth carbon of the next (see formula on page 403). This is known as "1-4 glucosidic linkage." There are also 1-6 linkages.

Phosphorylase acts on a terminal 1-4 linkage of the glycogen molecule, and an inorganic phosphate is joined to it, setting free glucose-1-phosphate, thus shortening the glycogen chain by one glucose unit. This is a reversible process, and according to the concentration of glucose-1-phosphate, the glycogen chain will be lengthened or shortened, *i.e.*, glycogen will be synthesized or broken down.

Phosphorylase catalyzes only the formation or breaking of 1-4 linkages; another, so far little-known, enzyme acts on 1-6 linkages of glycogen.

The reversible transformation of glycogen ⇌ glucose that takes place in the process of carbohydrate metabolism is due to phosphoryla-

[1] Leloir, R. F., R. E. Trucco, C. E. Cardini, A. Paladini, and R. Caputto, *Arch. Biochem.*, **19**, 339, 1948; **22**, 87, 1949.

tion; glycogen, however, can also be broken down by amylase, which breaks the glucosidic linkages by adding water instead of phosphate.

The formation of pyruvic and lactic acids. Glucose-6-phosphate not only may be converted into glycogen, but it may also follow a catabolic path which leads by a series of reactions to the formation of pyruvic acid. In this series fructose diphosphate is formed by phosphorylation with ATP. This molecule is then split into two molecules of triosephosphate, and adenosinephosphate is charged twice, by reacting with diphosphoglyceric acid and with phosphopyruvic acid. ATP is in this manner resynthesized, and it can then take part in the phosphorylation of another glucose molecule or in other reactions.

Di-phosphopyridin nucleotide (DPN) or coenzyme I (see Chap. 34) also takes part in these processes. This substance can be present in the oxidized or reduced form. The latter ($DPNH_2$) has two more hydrogen atoms than the former. In the oxidation of phosphoglyceraldehyde, coenzyme is reduced, DPN → $DPNH_2$, and in the reduction of pyruvic acid to lactic acid the reverse occurs, $DPNH_2$ → DPN.

Direct oxidation of glucose-6-phosphate. A less well-known process undergone by glucose-6-phosphate is its oxidation into phosphogluconic acid, which is converted into ribose-phosphate.

The formation of glucose. A very active phosphatase has been found, especially in the liver, which hydrolyzes glucose-6-phosphate into glucose and inorganic phosphate. Three enzymes take part in the conversion of glycogen into glucose in the liver: phosphorylase, phosphoglucomutase, and phosphatase. Amylase perhaps also takes some part in this process.

The role of adenosinephosphate. Muscular contraction is produced by the interaction of adenosine-

triphosphate (ATP) and actomyosin, one of the proteins in muscle. Chemical energy set free from ATP is converted into mechanical energy, the muscle contracts, and ATP loses some of its phosphate. Probably ATP acts as a source of energy in many other physiologic processes; therefore the origin of this substance is of great interest.

Adenosinephosphate is found in the tissues in three degrees of phosphorylation, *i.e.*, as adenosinemonophosphate (AMP), as adenosinediphosphate (ADP), and as adenosintriphosphate (ATP). When AMP accepts one phosphate group it is converted into ADP, which on accepting a second phosphate becomes ATP. This charging of adenosinephosphate cannot be done with inorganic phosphate; it is realized by the interchange of phosphate combined with other substances. Several phosphorylation reactions take place without adenosinephosphate (see diagram on page 403). Conversion of glycogen to glucose-1-phosphate and oxidation of phosphoglyceraldehyde to diphosphoglyceric acid are carried out by the direct introduction of inorganic phosphate. In anaerobic conversion of glycogen to lactic acid, adenosinephosphate acts as a phosphate donor in the production of fructosephosphate and as phosphate acceptor in reactions with 1–3 diphosphoglyceric acid and with phosphopyruvic acid. As each hexose molecule gives rise to two triose molecules for each glucose unit derived from glycogen, adenosinephosphate is charged three times with phosphate (two phosphates are obtained from diphosphoglyceric acid and two from phosphopyruvic acid, and one is lost in the phosphorylation of fructose phosphate). If the reaction begins with free glucose instead of glycogen, only two charges of phosphate are available, because one is lost in the initial phosphorylation of glucose.

Oxidation of glucose in oxygen gives rise to a considerably greater process of phosphorylation; there are approximately 36 charges of phosphate for each glucose molecule oxidized. The intimate mechanism of aerobic phosphorylation is not yet clearly understood, but undoubtedly it is a much more efficient process than anaerobic phosphorylation. This greater efficiency is also evident in thermodynamic studies; the oxidation of one glucose molecule sets free 680 kg.-cal., while its conversion to lactic acid gives rise to only 54 kg.-cal.

THE BLOOD SUGAR

Distribution of glucose in the body fluids. Glucose is dissolved in the water of all extracellular body fluids in approximately the same concentration, because of its great diffusibility. If a subject has 1 gm. of glucose per liter of blood plasma, there will be approximately 20 gm. in all the extracellular fluids, of which 5 gm. will be in the blood plasma and 15 gm. in the tissue fluids; the latter is therefore the principal store of glucose as such.

The sugar in the blood is D-glucose; on dissolving, an equilibrium is rapidly established between two isomers α- and β-glucose, which have been obtained in the pure form.
α-d-GLUCOSE	β-d-GLUCOSE
H-C-OH	HO-C-H
H-C-OH	H-C-OH

MP = 146°	MP = 148–150°

EQUILIBRIUM AT

$[\alpha]D = 52 \cdot 5°$

Glucose is in a free and diffusible form in the blood; this has been demonstrated by ultrafiltration *in vivo* (Brull) and by the vividiffusion method of Abel. An even more decisive proof is given by the fact that the glucose concentration in glomerular fluid is the same as that in blood plasma (Richards, Walker; see Chap. 63).

Acid hydrolysis of blood plasma causes the formation of the so-called "protein sugar," called "galactoglucosamine-mannose" (Bierry).[1] The metabolic significance of this substance is as yet unknown. Glucose is the principal sugar found in blood plasma; there are only very small amounts of other sugars (fructose). In rare abnormal cases fructose and lactose appear in the urine; the appearance of the latter is related to the function of the mammary gland. Pentoses are sometimes found in the urine. In blood plasma a small amount of a volatile reduc-

[1] BIERRY, H., and F. RATHERY, "Introduction à la physiologie des sucres," J. C. Baillière et fils, Paris, 1835.

ing substance has been found; it is apparently acetaldehyde.

In the estimation of blood sugar by the usual methods, glucose concentration is calculated by the reducing activity of the blood or plasma filtrates.[1] This gives the apparent glucose concentration; real glucose is less than this, because 20 to 27 per cent of the reducing activity is due to other substances, such as creatinine, thioneine, glutathione, etc.[2] The real concentration of sugar is obtained by measuring the reducing power before and after submitting the plasma to the enzymatic action of brewer's yeast, which destroys glucose without altering other reducing substances. The concentration of glucose is the same in the water of the plasma and the erythrocytes, but the latter contain about 20 per cent less glucose because they have a higher protein concentration, and therefore less water than plasma.

Glucose is rapidly broken down in shed blood (glycolysis), and lactic acid is formed. Glycolysis is due mainly to the blood cells. Therefore, when determining the blood sugar, proteins should be precipitated immediately after the blood is drawn, or else the blood should be dried on filter paper or by anhydrous Na_2SO_4; otherwise part of the glucose will be destroyed. Glycolysis can also be partially inhibited by fluoride or monoiodoacetate.

The fasting blood sugar, as determined by current methods, varies between 70 and 100 mg. per cent. These figures correspond to the reducing activity of the blood or plasma; the real concentration of glucose is only 50 to 80 mg. per cent. This is the normal blood-sugar level. A concentration above the normal maximum (usually fixed at 120 mg. per cent) is called hyperglycemia; concentrations below the normal minimum are known as hypoglycemia.

Sugar-tolerance curves. During the absorption period following digestion the blood sugar rises, but never above 160 mg. per cent in normal subjects. If 50 to 100 gm., or 1 gm. per kg. of body weight, glucose is given by mouth to a normal individual, the blood sugar rises, reaching a maximum level not greater than 170 mg. per cent, in about 30 min.; afterward the blood sugar falls slowly, returning to the initial level in about 2 hr. (Fig. 193). Frequently a drop below the normal is observed after the rise, with a subsequent return to the initial level.

[1] See technical manuals for the techniques used.

[2] Somogyi, M., *J. Biol. Chem.*, *75*, 33, 1927; **78**, 117, 1928. Reducing substances that are not glucose are more abundant in the erythrocytes (about 40 mg. per 100 ml.) than in plasma (10 mg. per 10 ml.). Modern improved techniques for blood-sugar analysis exclude more and more reducing substances that are not glucose.
Fig. 193. Blood-sugar curves following the ingestion of glucose (1 gm. per kg. of body weight) in a normal subject and in three cases of diabetes. As the severity of diabetes increases the blood sugar rises to a higher level and remains high for a longer time.

The blood-sugar curve thus obtained is conditioned by the time taken to reach the intestine, the speed of absorption, and the mechanisms that control carbohydrate metabolism. The curve may be prolonged and flattened by retarded gastric evacuation or slow intestinal absorption (thyroid, adrenal, or hypophyseal insufficiency). It is higher and more prolonged in diabetes. The subject is considered to be suffering from diabetes if the blood sugar is above 130 mg. per cent when fasting, and rises to 180 mg. per cent or more ½ hr. after the ingestion of 50 to 100 gm. glucose, without returning to the normal level in 3 hr. In hyperthyroid subjects the blood-sugar curve is higher than the normal after the ingestion of glucose, and especially of galactose (Althausen), owing to the increase in the speed of absorption of these sugars in this condition. For this reason a hyperthyroid subject should not be considered diabetic unless the blood sugar when fasting is 150 mg. per cent or more and rises to 200 mg. per cent after the ingestion of glucose.

The blood-sugar curve following the ingestion of glucose is known as the sugar-tolerance curve. It is conditioned by the previous diet of the subject;[1] the blood sugar rises less in subjects fed a diet rich in carbohydrates, and more in those fed a diet poor in carbohydrates (Fig. 194).

[1] Himsworth, H. P., *Brit. M. J.*, **1**, 719, 1940.

Until recently it was believed the previous diet modified only the response of the liver, but in eviscerated rats the peripheral (extrahepatic) tissues burn preferentially the principal constituent of the previous diet, either fats or carbohydrates.[1]

FIG. 194. Effect of carbohydrate content of previous diet on the peripheral utilization of glucose. Two experiments in the same normal subject; in each experiment 50 gm. glucose was given by mouth. The area between the arterial and venous blood-sugar curves is approximately the same in both experiments; this suggests that in both cases the same amount is removed from the blood by the tissues. [*Himsworth, H. P., Lancet, vol. 55 (2), p 118, 1939.*]

If the dose of glucose is given in two parts, the second dose is not followed by a rise in blood sugar (Hamman and Hirschmann, 1919; Staub and Traugott, 1922).[2] The Exton-Rose[3] test is based on this fact. The subject is given 50 gm. of glucose by mouth, and 30 min. later another 50 gm. The blood sugar does not rise above 160 mg. in the first hour in nondiabetic subjects; in diabetic ones, it rises above 180 mg., and in doubtful cases it rises to 160 to 180 mg. per cent.

The capacity to assimilate glucose has also been measured, but less frequently, by continuous intravenous injection of glucose. In normal subjects a dose of 0.5 to 0.75 gm. per kg. of body weight per hour does not produce glycosuria, while 0.9 gm. per kg. per hr. usually does. When the administration of glucose by mouth is followed by an abnormal tolerance curve and the intravenous injection of glucose gives a normal curve, there is a disturbance in the absorption of carbohydrate, but utilization of sugar (glucose or galactose) is normal.

Ingestion of 150 to 200 gm. glucose seldom provokes glycosuria, and there is never any considerable loss of sugar in the urine even with larger doses (300 to 500 gm.). These tests involving the provocation of alimentary glycosuria are not often performed now, because the determination of the fasting blood sugar and the tolerances curves are of greater value in the examination of carbohydrate metabolism.

The difference in glucose concentration of arterial and venous blood is established by determining glucose in samples obtained at the same time from an artery or by venous puncture. This does not give an accurate idea of the rate of glucose consumption by the tissues, because the speed with which the blood circulates is an important factor in this difference.

Insulin-tolerance curves are obtained by injecting a dose of this hormone and following the changes in blood sugar, noting the degree and duration of hypoglycemia and the time taken to recover the normal level. Himsworth reports that in subjects fed a previous diet with a high carbohydrate content, insulin has a more marked effect than in subjects on a low carbohydrate diet.

THE REGULATION OF CARBOHYDRATE METABOLISM

The Regulation of the Blood-sugar Level

The concentration of glucose in blood is an important index of carbohydrate metabolism. The blood-sugar level is dependent on the balance between glucose entering and that leaving the blood. Glucose entering the blood stream (Fig. 192) comes from (*a*) digestive absorption, or subcutaneous or intravenous injection of glucose; (*b*) glucose in the tissue fluids; (*c*) secretion of glucose by the liver. Glucose leaves the blood stream by (*a*) diffusion into the tissue fluids; (*b*) storage as glycogen in the liver, muscles, etc.; (*c*) conversion into fat; (*d*) combustion in the tissues with the formation of CO_2 and water; (*e*) in certain cases, renal excretion.

Digestive absorption of glucose has already been considered. The tissue fluids are a vast store of free glucose in equilibrium with the blood plasma. Absorbed or injected glucose rapidly passes into the tissue fluids, where it is temporarily stored.[1] Part of it is then taken up by the cells, which burn or store it, and part diffuses back into the blood. The tissue fluids also, at times, receive glucose from cells where it has been stored, and from there sugar diffuses into the blood.

The main processes of carbohydrate metabolism can be summarized as follows: The liver secretes glucose into the blood stream, from which it diffuses into the tissue fluids. Glucose is then consumed by the tissues, especially by the muscles, which form 45 per cent of the body weight. The formation and consumption of glucose are controlled by endocrine (pancreatic, anterior hypophyseal, adrenal, etc.) and nervous factors.

[1] Cannon refers to this as storage by flooding, in contrast to storage by segregation, which consists in the conversion of glucose into glycogen.

Fig. 195. Fall in blood sugar following hepatectomy in chloralosed dogs. Average figures of four animals with pancreatic diabetes, five with metathyroid diabetes, five with meta-alloxan diabetes, four with metahypophyseal diabetes, and five normal animals.

The Role of the Liver

The liver is the central organ in carbohydrate metabolism and the main factor in the control of the blood-sugar level. Its principal functions in this respect are (*a*) the secretion of glucose into the blood stream, thus maintaining the blood-sugar level; (*b*) the formation of glycogen within the hepatic cells when there is hyperglycemia, and the breaking down of glycogen when there is hypoglycemia; (*c*) the conversion of fructose, galactose, mannose, and lactic and pyruvic acids into glycogen, which is broken down and secreted as glucose when needed, whatever the substances used in its formation; (*d*) glyconeogenesis, *i.e.*, formation of glucose from noncarbohydrate substances (protein, etc.).

The liver is the organ that forms the blood sugar. This has been proved in many experiments. For example, if the liver is removed completely without disturbing the circulation,[1] the blood sugar immediately commences to fall continuously, even in diabetic animals (Fig. 195), and severe symptoms appear when the hypoglycemia is marked. Intravenous injection of glucose will allow the animal to recover; it can

[1] Mann, F. C., *et al.*, *Am. J. Physiol.*, **65**, 403, 1923: **103**, 45, 1933; *Medicine*, **6**, 419, 1927.

again stand and walk, but sugar is being constantly consumed, so that it is necessary to inject glucose continuously at the rate of 200 mg. per kg. per hr. to maintain a normal blood-sugar level in the hepatectomized or eviscerated dog.[1] Hyperglycemia cannot be provoked in any way in hepatectomized animals except by the injection of glucose; *e.g.*, anesthesia, asphyxia, pancreatectomy, the injection of adrenaline or anterior hypophyseal extracts, etc., do not cause the blood sugar to rise.

The liver plays its part in blood-sugar regulation by keeping a balance between the amount of glucose it secretes into the blood and the amount it takes from the blood and stores as glycogen. During digestive absorption, blood in the portal veins has a higher glucose concentration than blood in the suprahepatic veins; therefore the liver glycogen increases. During fasting the opposite conditions are observed (Claude Bernard). Quantitative determinations of the intake and output of sugar by the liver have shown that there is normally a continuous output of glucose. When the blood sugar rises the hepatic secretion of sugar ceases and glucose is retained by the liver (Fig. 196). On the contrary, in hypoglycemia the liver discharges glucose into the blood, thus raising the blood-sugar level. Soskin[1] has made a careful study of this aspect of hepatic homeostasis.
Fig. 196. Hepatic homeostasis. Effect of intravenous injection of glucose (175 gm. per kg.) on the intake and output of glucose by the liver of a dog. Right ordinate, arterial blood sugar, mg. per cent. Left ordinate, liver intake and output, mg. per min. Abscissa, hours. Broken line, arterial blood sugar; heavy solid line, intake (below the 0 level) and output (above) in milligrams per minute. Glucose output ceases immediately when sugar is injected, then considerable amounts are taken up. Throughout the second hour the liver neither retains nor excretes glucose; during this period the blood sugar falls below the initial level and does not rise until the liver again excretes glucose into the blood. Inhibition of hepatic sugar excretion is therefore a real phenomenon, distinct from storage of sugar. (*Soskin, S., et al., Am. J. Physiol., vol. 124, p. 558, 1938.*)

In certain abnormal conditions hepatic homeostasis is disturbed. Thus, in diabetes the liver does not cease to secrete glucose when there is a high blood-sugar level, and sustained hyperglycemia results. Conversely, in hypophyseal or adrenal insufficiency the liver does not increase the secretion of glucose when the blood sugar falls, and severe hypoglycemia is easily provoked by fasting.

A normal blood-sugar level is maintained in spite of the continuous consumption of glucose by the tissues. The amount of glucose stored as glycogen in the liver is enough for only a few hours; therefore blood glucose cannot arise exclusively from the glycogen stored at a given

[1] Houssay, B. A., C. Dosne, and V. G. Foglia, *Am. J. Physiol.*, **141**, 1, 1944.

[1] Soskin, S., *Physiol. Rev.*, **21**, 140, 1941.

moment but must be formed from other non-carbohydrate sources.

Blood in the renal vein sometimes has a higher glucose concentration than arterial blood. This has been considered as proof that the kidney secretes glucose.[1] Further evidence is given by the fact the blood sugar falls more slowly in eviscerated animals if the kidneys are not removed.

Formation, breakdown, and significance of liver glycogen. Hepatic glycogen is continuously being synthesized and broken down, so the glycogen content of the liver varies considerably. The ingestion of carbohydrates increases liver glycogen, and fasting decreases it.

The formation of glycogen (glycogenesis) can be studied in animals in which the store of glycogen in the liver has been previously depleted and reduced to a very low level by fasting, cold, convulsions, phlorhizin, etc. The substance to be tested is then administered to the animal, and the liver-glycogen concentration is again determined.[2]

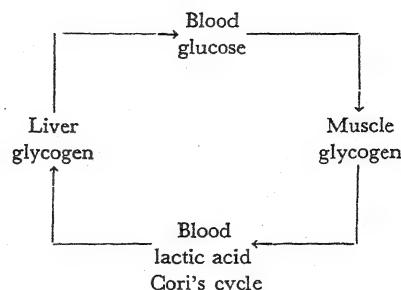
Administration of carbohydrate increases the glycogen content of the liver. Some carbohydrates produce this effect when they are given by mouth or injected into the blood stream (glucose, fructose, mannose, galactose, maltose, pyruvic and lactic acids, glycerol). Others must first be broken down by digestive processes (sucrose, lactose, starch); given by intravenous injection, they cannot be utilized by the organism and are eliminated in the urine. More glycogen is formed from fructose than from an equal amount of glucose; galactose is a much less efficient glycogen precursor.

In some cases an excess of muscle glycogen is broken down to lactic acid, part of which passes into the blood stream and is carried to the liver, where it is converted into glycogen. Hepatic glycogen is then broken down to glucose, which passes into the blood stream and is carried to the muscles, where it is utilized. This process, called "Cori's cycle," is observed in rats and young rabbits injected with adrenaline. It is also observed, although it is not important, during intense muscular exercise.

[1] REINECKE, R. M., *et al.*, *Am. J. Physiol.*, **140**, 276, 1943; 151, 198, 1947.

[2] An increase in liver glycogen does not necessarily signify that a substance administered to the animal has been converted into glycogen, because the increase may have been due to inhibition of the breakdown of glycogen formed from the blood sugar.

Blood glucose → Muscle glycogen → Blood lactic acid → Liver glycogen → Blood glucose

Cori's cycle


Liver glycogen is also formed by the administration of protein and some amino acids, but the rate of synthesis and the amount formed are less than when carbohydrate is given. Glycogen so formed is not originated mainly by direct conversion of protein into glucose or glycogen, because after the administration of glycine with a C isotope to a fasting mouse, the liver glycogen does not contain much C isotope.[1] Also the administration of alanine, marked by an isotope, to a diabetic animal causes the appearance in the urine of an excess of glucose which has little of the isotope in it.[2] Fats give rise to very small amounts of glycogen, which seems to be formed mainly from glycerol, but fatty acids, as has been shown by labeling them with an isotope, can also be converted into glycogen.

The amount of glycogen stored in the liver at a given moment is the balance resulting from the glycogen formed and that broken down. Glycogenolysis (glycogen breakdown) is due to a process of phosphorylation; it ends in the formation of glucose which passes into the blood.

Glycogenolysis occurs in the following circumstances: (*a*) increased consumption of glucose by the tissues (intense and prolonged exercise, cold); (*b*) hypoglycemia (phlorhizin, insulin, fasting, hypophyseal and adrenal insufficiencies); (*c*) acidosis; (*d*) pancreatic diabetes; (*e*) excess thyroid function or administration of thyroxine; (*f*) stimulation of the sympathicoadrenal system; (*g*) asphyxia or anoxia.

A normal concentration of glycogen in the liver is usually a sign of normal metabolism. A decrease in glycogen content renders the liver more susceptible to injury by toxic substances (chloroform, phosphorus); therefore prolonged fasting should be avoided before and after surgical operations. Liver glycogen diminishes

[1] OLSEN, N. S., A. HEMINGWAY, and A. O. NIER, *J. Biol. Chem.*, **148**, 611, 1943.

[2] GURIN, S., and D. W. WILSON, *Federation Proc.*, **1**, 114, 1942.

when the organism does not receive or cannot utilize a sufficient amount of carbohydrate. In this case energy is obtained from fat, and if there is an excessive breakdown of fat, ketone bodies are formed (ketosis and ketonuria of fasting, diabetes, etc.). The metabolism of some amino acids is also disturbed when there is not enough liver glycogen.

Muscle glycogen varies much less than liver glycogen. It decreases a little in hypoglycemia and increases when glucose is injected or there is hyperglycemia; insulin also increases it. Muscle glycogen cannot be utilized to maintain a normal blood sugar after the liver has been removed. Muscle glycogen falls rapidly to a low level during fasting in hypophyseal and adrenal insufficiency (not so rapidly in the latter). Decrease of muscle glycogen can be controlled by administration of the hypophyseal growth hormone; also of certain corticoadrenal hormones (glycocorticoids).

Muscular contraction causes a sharp and marked decrease in muscle glycogen, especially if there is intense, prolonged, and repeated contraction, or a sustained tetanus. During rest muscle glycogen is rapidly resynthesized. In pancreatectomized or in adrenalectomized animals, muscle-glycogen resynthesis during rest proceeds at a much slower rate than in normal animals (Fig. 198). Insulin and some of the corticoadrenal hormones increase the rate of muscle-glycogen formation and sometimes raise the basal level of muscle-glycogen content.[1]

In endocrine insufficiencies (pancreatic, adrenal, etc.) and in hyperthyroidism, disturbances in muscle and liver glycogen appear in the following order: (*a*) liver glycogen decreases, and little or none is formed after glucose injections; (*b*) less muscle glycogen is formed after glucose injection, and the rate of muscle-glycogen resynthesis after it has been depleted by tetanization is decreased; (*c*) in an advanced stage the basal or resting level of muscle glycogen is also decreased.

The Role of the Kidney

There is no appreciable quantity of glucose in normal urine,[2] but when the blood sugar rises to a level near 170 mg. per cent (from 150 to 190 mg. per cent in different cases) glycosuria occurs. The blood-sugar level at which glycosuria occurs is known as the renal threshold for glucose.[1] The following process takes place in the kidney: (*a*) glucose is ultrafiltrated through the glomerulus and is found in glomerular fluid in the same concentration as in blood plasma; (*b*) glucose is then completely reabsorbed by the proximal convoluted renal tube (Richards, Walker). The maximum capacity of tubular reabsorption of glucose (Tm_G) is approximately 375 mg./min. in man and 303 mg./min. in woman (Smith). If the amount filtered by the glomerulus exceeds this maximum, glycosuria occurs. In cases of diabetes that have lasted for some time, the maximum reabsorption capacity may be above the normal and glycosuria does not occur in spite of the existence of moderate hyperglycemia (see pages 726 and 737).

Certain drugs, *e.g.*, phlorhizin,[2] suppress tubular reabsorption of glucose and therefore provoke glycosuria. The effect of phlorhizin is attributed to the inhibition of phosphorylation of glucose in the renal tubes, a process which is necessary for it to be reabsorbed. The role of the kidney therefore consists in preventing the loss of glucose filtered through the glomerulus, thus avoiding a serious metabolic disturbance.

Phlorhizin injections cause intense glycosuria, which persists in the fasting animal. Glucose thus excreted comes from carbohydrate ingested, glycogen broken down, and glyconeogenesis. In prolonged fasting its only source is glyconeogenesis. Excess protein catabolism thus caused is followed by an increase in the excretion of urinary nitrogen. The increase in fat consumption causes a large production of ketonic bodies, which cannot all be metabolized; the excess accumulates in the blood or is excreted in

[1] Endocrine regulation of muscle-glycogen formation has been studied by Foglia, Fernández, Mazzocco, Dambrosi, and Leloir (see *Rev. Soc. argent. de biol.*) and by Long, Lukens, Kendall, Ingle, and others.

[2] The concentration of glucose in normal urine is always below 2 mg. per cent (van Slyke); there are reducing substances in urine which contribute to its slight reducing effect. Fehling's and Benedict's solutions are not appreciably reduced by normal urine.

[1] When there is hyperglycemia and the blood sugar falls, glucose is excreted by the kidneys even when the blood sugar has fallen to levels below 170 mg. per cent; on the other hand when blood sugar rises the threshold is higher and in some abnormal cases it can be as high as 220 mg. per cent. The renal threshold for a rising blood sugar is therefore higher than that for a falling blood sugar.

[2] Phlorhizin is a glucoside extracted from the cortex of apple-tree roots; on hydrolysis it splits into glucose and phloretine.

the urine. This condition is known as "phlorhizin diabetes" because there is glycosuria, ketonuria, and excess urinary N. There are several differences between this type of diabetes and human or other experimental diabetes: (*a*) in phlorhizin diabetes the blood sugar is below normal and there is no hyperglycemia as in other diabetic states; (*b*) administration of sugar is followed by a greater consumption of sugar. In phlorhizin diabetes insulin is secreted by the pancreas, but insulin secretion may be depressed (Houssay and Foglia). When glucose is given to an animal with phlorhizin diabetes, a large part of it is excreted in the urine. The administration of glycogenic amino acids (those which form glucose) is followed by an increase in glycosuria; administration of ketogenic amino acids (those which give ketone bodies) is followed by an increase in ketonuria (see Chap. 43, Protein Metabolism).

In certain human cases of so-called renal diabetes there is glycosuria with normal blood-sugar levels. This disturbance is attributed to deficient reabsorption of glucose by the renal tubes. Some cases of slight glycosuria in pregnancy are apparently produced by a similar mechanism. In pregnant women glycosuria is provoked by small doses of phlorhizin which do not cause glycosuria in non-pregnant women.

ENDOCRINE REGULATION OF CARBOHYDRATE METABOLISM

All living cells can utilize glucose, but in higher animals the production and consumption of glucose, and therefore the blood-sugar level, are controlled by several endocrine factors. These are the secretions of the pancreas, anterior hypophysis, adrenals, and thyroid; other glands play a lesser part. These endocrine glands do not function in an isolated way; they are coordinated in a regulatory mechanism, so that carbohydrate metabolism is controlled by an endocrine balance. Hormones secreted by these glands regulate the storage and secretion of glucose by the liver and the consumption of glucose by the tissues, and they contribute to the maintenance of the normal blood-sugar level and of the normal glycogen concentration in liver and muscle. Reciprocally the blood-sugar level controls the secretion of insulin by the pancreas and that of glucose by the liver, and perhaps the secretions of other endocrine glands that take part in the regulation of carbohydrate metabolism.

The Role of the Pancreas

The importance of the pancreas in carbohydrate metabolism was brilliantly demonstrated by von Mering and Minkowski (1889) when they showed that pancreatectomy in the dog causes a severe diabetes, usually fatal in 1 or 2 weeks, although sometimes in 4 weeks or more. If 12 per cent (one-eighth) of the pancreatic tissue is left in the dog, and 5 to 10 per cent in the rat, the animal does not become diabetic and the blood sugar remains normal. A pancreas thus surgically reduced is not as resistant as the whole pancreas, and it is easily damaged by many agents, such as the administration of anterior hypophyseal extract[1] or thyroid.[2] In some cases—frequently, in the rat—the remaining pancreatic tissue degenerates spontaneously and the animal, after a few months, gradually becomes diabetic; the severity of the condition usually increases as time passes, but sometimes there is spontaneous recovery and the blood sugar returns to a normal level.

The removal of more than seven-eighths of the pancreas in dogs provokes a mild type of diabetes, known as Sandmeyer's diabetes. This condition is not stationary; either the remaining islets degenerate progressively and the severity of diabetes increases until the animal dies, or else the islets improve and increase, the blood sugar eventually returning to normal.

Diabetes following pancreatectomy has been observed in fishes, amphibians, reptiles, birds, and mammals, but there are considerable differences in the severity of the disorder and the length of survival in different species. In the dog and cat this type of diabetes is very severe and rapidly fatal. It progresses more slowly in the rat, monkey, and pig. In some birds (owl) it is very severe; in others (duck) it is so mild that there is scarcely any metabolic disturbance.

Total extirpation of the pancreas has been performed for therapeutic purposes (cancer, etc.) in some twenty patients; severe diabetes occurred in all these cases.

Pancreatic diabetes is due to the elimination of the function of the Langerhans islets.[3] The β cells of the islets secrete insulin, the pancreatic hormone. Damage of the β cells causes diabetes. These statements are based on the following facts:

[1] Houssay, Biasotti, and Rietti, 1932.

[2] Houssay and De Finis, 1943; Houssay, 1944 and 1945.

[3] Diamare, 1889; Laguesse, 1893.

1. Ligature of the pancreatic ducts provokes atrophy of the exocrine (zymogenous) cells, usually without damaging the islets; this operation does not cause diabetes.[1]
2. Repeated injections of anterior hypophyseal extract produces hypophyseal diabetes; if the treatment is sufficiently prolonged, diabetes becomes permanent (metahypophyseal diabetes). In the first case the β cells are severely damaged, and in the second there are irreversible lesions in these cells, which lead to widespread atrophy of the islets. The exocrine cells remain in good condition.
3. Certain toxic substances, such as alloxan,[2] produce lesions in the β cells of the islets, destroying many of them, but leaving the α cells undamaged; these substances produce diabetes.
4. Prolonged hyperglycemia, maintained for several days in cats by intraperitoneal injections of glucose, causes hydropic lesions in the β cells and in some cases permanent diabetes.
5. In all types of experimental diabetes in which the pancreas is not removed, severe and widespread damage to the β cells is observed. Lesions progress by the following stages: degranulation, hydropic degeneration, atrophy, and finally disappearance of the β cells.
6. In 80 per cent of human cases of diabetes, lesions of the β cells have been observed. Lesions are found in these cells in only 16 per cent of nondiabetic subjects. Insulin controls hyperglycemia, glycosuria, and acidosis in all forms of human diabetes.
7. Considerable amounts of insulin have been extracted from the giant islets of certain fishes and from tumors formed by islet tissue in human cases of hyperinsulinism.[1] Some of these tumors are malignant, and metastases of the same tissue in the liver yield large quantities of insulin, which is not obtained from the surrounding hepatic tissue.

The following experiments demonstrate the secretion of insulin by the pancreas: (*a*) pancreatectomy causes diabetes (Fig. 197); (*b*) a pancreatic graft, made by joining the pancreatic artery and vein to the carotid and jugular vein of a diabetic dog, provokes a decrease of the blood sugar to the normal level; (*c*) if the graft is made immediately after pancreatectomy while the blood sugar is normal, hyperglycemia does not occur (Fig. 197); (*d*) this graft also restores the normal concentration of glycogen in the liver and muscle (Fig. 198), secretes adequate amounts of insulin, and performs all the endocrine functions of the pancreas;[2] (*e*) injection of pancreatic venous blood produces a fall in diabetic hyperglycemia, whereas injection of blood from the general circulation does not have

Fig. 197. Effect of a pancreatic graft on the blood sugar. Each curve represents the average blood sugar of several dogs. Left curve, three pancreatectomized diabetic dogs; the arrow indicates the establishment of the graft. Middle curve, four pancreatectomized dogs which were grafted immediately after the removal of the pancreas. Right curve, five pancreatectomized dogs which did not receive a pancreatic graft. (*Houssay, Lewis, and Foglia, Rev. Soc. argent. de biol., vol. 4, p. 859, 1928.*)

this effect;[1] (*f*) daily injections of insulin and an adequate diet have permitted totally pancreatectomized dogs to survive up to 5 years.[2] A normal blood-sugar level has been maintained by insulin treatment in patients who have suffered total pancreatectomy.

Insulin. Insulin is the pancreatic hormone. It was discovered and extracted from pancreatic tissue by Banting and Best in 1922[3] and obtained in crystallized form by Abel (1926). It is a protein; its molecular weight has been reported to vary between 6,000 and 48,000,[4] being made up of units weighing 6,000 or 12,000 each. Determinations of molecular weight of insulin in the solid state made by the x-ray method give a maximum weight of 36,000.[5] This figure agrees with the value of 35,000 to 36,000 found by ultracentrifugation and diffusion of pure insulin solutions.[6] Eleven amino acids have been found in it. It contains sulfur (3.3 per cent), and it loses its activity if the —S—S— bond is broken. It crystallizes as a zinc salt (Scott) and also with cobalt and cadmium. So far it has not been possible to extract insulin from tissues other than the pancreas. International standard insulin has 23 units per mg., but purified insulin containing 27 to 30 units per mg. has been obtained.

Insulin preparations are standardized by biological methods based on their hypoglycemic activity. Two criteria are used for this purpose: (*a*) the average maximum fall in blood sugar produced by the injection of the extract in a series of rabbits; (*b*) the percentage of white mice that have hypoglycemic convulsions after injection of the extract. Sensitiveness of the animals varies, so it is necessary to compare the effect of the unknown extract with that of the international standard insulin.

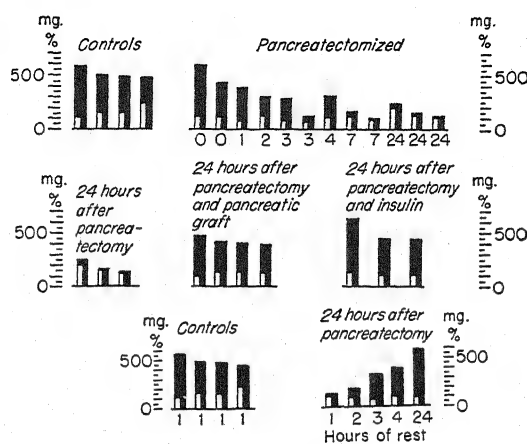
Insulin secreted by the pancreas has the following physiologic effects: (*a*) it maintains the normal blood-sugar level and prevents hyperglycemia (Fig. 197); (*b*) it controls the secretion of glucose by the liver; (*c*) it regulates the production of glucose from noncarbohydrate sources such as amino acids (glyconeogenesis); (*d*) it maintains a normal liver- and muscle-glycogen concentration (Fig. 198); (*e*) it increases the rate of sugar consumption of the tissues; (*f*) it controls the production of ketonic bodies; (*g*) in diabetic patients it controls most of the specific metabolic disturbances.


FIG. 198. Resynthesis of muscle glycogen after fatigue. Each column represents the average muscle glycogen of one dog in milligrams per 100 gm. Inset in white, glycogen immediately after fatigue; in black, glycogen after 1 hr. rest, except in the last group where the duration of rest in hours is given under each column. (*Dambrosi, R. G., Rev. Soc. argent. de biol., vol. 9, p. 430, 1933.*)

Insulin is destroyed by the digestive secretions; therefore it loses almost all its activity when given by mouth and must be given by intravenous or subcutaneous injection. These injections cause the blood sugar to fall in normal and in diabetic subjects. The fall is more rapid after intravenous injections and lasts longer after subcutaneous ones. Diabetic patients are usually treated by subcutaneous injections, because they are simpler and have a more prolonged effect. After a few hours the blood sugar rises gradually to the initial level. The level of hypoglycemia and its duration depend on the amount of glucose available, obtained by absorption from the intestine, mobilization of stored glycogen, or production in the liver. There will be little or no hypoglycemia if there are large quantities of glucose available; on the contrary, hypoglycemia will be marked and prolonged if there is little glucose available.

Intense and prolonged hypoglycemia is

[6] CREETH, J. M., *Nature*, **170**, 210, 1952.

typical of sensitiveness to insulin; in cases of insulin resistance there is little or no fall in blood sugar. Insulin causes a more marked decrease in blood sugar in subjects previously fed a diet rich in carbohydrates, and a less marked decrease in those fed a diet rich in fat. An intense and prolonged fall in the blood-sugar level gives rise to hypoglycemic symptoms (see Hypoglycemia, page 419).

Insulin increases carbohydrate utilization by the organism. Glucose consumption increases owing to (*a*) increased combustion of glucose (the RQ rises); (*b*) increased formation of muscle glycogen, especially marked if the glycogen store had been previously depleted;[1] (*c*) conversion of glucose into fat. This last is an important effect of insulin, which does not take place in diabetic subjects and is the cause of the scarcity and even complete absence of fat deposit in severe diabetes (Stetten). Plasma phosphate and potassium diminish during insulin hypoglycemia because they are taken up by the tissues. The passage of phosphate to the muscles is particularly marked.[2]

Liver glycogen usually diminishes during insulin hypoglycemia. It increases only in diabetic animals. The decrease in liver glycogen is due to its breakdown caused by the fall in the blood-sugar level. Glucose injections prevent the decrease in liver glycogen, but in nondiabetics there is no more glycogen formed after glucose injections given with insulin than when glucose without insulin is injected.

This mobilization of liver glycogen is due to the direct effect of hypoglycemia on the liver and to the stimulation of the sympathicoadrenal mechanism. The sympathetic nerve centers are stimulated by hypoglycemia and discharge impulses along the hepatic nerves and the nerves to the adrenals. This causes the breakdown of glycogen in two ways—directly, by a nervous effect on the liver, and indirectly, by the discharge of adrenaline from the adrenal medulla. Suppression of the sympathicoadrenal mechanism retards the recovery of the normal blood-sugar level after insulin hypoglycemia.

Insulin diminishes the secretion of glucose by the liver when the blood sugar is normal and also in hypoglycemia. Normal hepatic homeostasis is disturbed by insulin; thus hypoglycemia normally causes an increase in the secretion of glucose by the liver (Soskin), but insulin hypoglycemia does not. Insulin hypoglycemia is not due mainly to an increase in glucose consumption, because intense muscular exercise causes a much greater increase without provoking hypoglycemia. In this case the liver increases the secretion of glucose into the blood, but this does not occur in insulin hypoglycemia. In the diabetic liver, insulin also diminishes the formation of glucose from protein and fat, *i.e.*, glyconeogenesis.

Insulin does not act exclusively on the liver; it also has a direct effect on the tissues. In the eviscerated dog, insulin accelerates the fall in blood sugar; it increases the rate of glucose consumption and the storage of muscle glycogen. This has also been observed *in vitro* in slices of rat diaphragm surviving in Ringer's fluid with added glucose (Gemmill).[1] Muscle can form glycogen when there is no insulin, but at a slower rate than the normal.

Insulin treatment produces a resting condition in the islets, thus favoring regeneration of damaged cells, and protects them from the unfavorable effects of hyperglycemia. The damaged cells can recover if the lesions are not too severe. The histologic aspect, insulin content, and secretion then return to normal. If the damage is so severe that cells are destroyed and the islets atrophied, insulin is no longer efficacious.

The effect of insulin is antagonized by several factors: infections; acidosis; anterior hypophyseal, corticoadrenal, and thyroid hormones; certain anesthetics (anoxia); the existence of anti-insulin; and functional disturbances in the liver. In all these cases there is insulin resistance, and large doses must be given to obtain the usual effects. Probably all these factors modify the sensitiveness of enzymatic systems in the cells. A diet rich in fats requires more insulin than a diet rich in carbohydrate.

The intimate process by means of which insulin exerts its activity is not yet completely understood. Apparently it promotes the passage of glucose from interstitial fluids into the

[1] In order to observe the effect of insulin on muscle-glycogen resynthesis, it is necessary to denervate the muscle, because hypoglycemia may cause convulsions, and muscular contractions thus provoked deplete the muscle-glycogen store.

[2] Sacks, J., *Am. J. Physiol.*, **143**, 157, 1945.

[1] Stadie, W. C., and J. A. Zapp, *J. Biol. Chem.*, **170**, 55, 1947.

cells, with the formation of glucose-6-phosphate catalyzed by hexokinase. It also favors the synthesis of fatty acids through the tricarboxylic cycle, decreasing the oxidation of fats.

The insulin content of the pancreas. There is positive correlation between the number of islets in the pancreas, the condition of the β cells, and the insulin content.[1] The insulin content of the pancreas is diminished during fasting, with a fat diet, or by repeated injections of insulin, but again increases when the animals are fed carbohydrate or mixed diets. Pancreatic tissue remaining after partial pancreatectomy has a normal insulin content; but the insulin content diminishes if the animals are treated with substances that damage the islets, such as anterior hypophyseal extract, alloxan, excess sugar, thyroid, etc.[2] The normal pancreas has approximately 2 units of insulin per gram; the content of normal islets has been estimated at 150 units per gm. The insulin content of the pancreas of diabetic subjects varies considerably; an average of 0.4 units per gram has been reported. In a case of an islet adenoma with symptoms of hyperinsulinism, 85 units of insulin per gram was found. Estrogens, thyroid, and anterior hypophyseal extract in certain doses provoke hypertrophy and hyperplasia of the islets, especially in the rat. It should be noted that large doses of thyroid and anterior hypophyseal extract damage the β cells, causing degeneration and atrophy of the islets, and thus produce diabetes. All these factors—partial pancreatectomy, excess sugar, anterior hypophysis, and thyroid—are supposed to first stimulate the islet cells and then exhaust them, causing degeneration and a decrease in insulin production. Persistent hyperglycemia, rapid growth, a high metabolic rate, and a high caloric diet are factors that concur in exhausting the islets.

Insulin secretion. The concentration of a hormone in a gland does not always give an accurate idea of the amount secreted into the blood. To measure the rate of secretion it is necessary to estimate the concentration in the blood leaving the organ, together with the circulation rate. Insulin determinations in arterial or venous blood have not given completely satisfactory results: they are usually made in diabetic hypophysoadrenalectomized mice or rats, which are known to be very sensitive to insulin. According to Gellhorn[1] the concentration of insulin in the blood of normal subjects is from 0.0001 to 0.0002 unit per cubic centimeter. Insulin disappears from the blood after pancreatectomy in dogs.

The amount of insulin secreted by the pancreas has been estimated by the method of substitution in pancreatectomized animals and in diabetic patients. Continuous intravenous injection of insulin during 12 hr. in recently pancreatectomized dogs maintains a normal blood sugar when the dose is from 0.005 to 0.035 (average 0.017) unit per kilogram per hour; an excessive amount provokes hypoglycemia, and an insufficient amount does not prevent the rise in blood sugar.[2] These doses correspond to a secretion of 30 to 50 units daily for a fasting man of 70 kg. Recent determinations made in pancreatectomized patients have shown that 26 to 80 (average 42) units is required daily to maintain a normal blood sugar when the patient is given 150 to 300 gm. of glucose.[3] It is remarkable that insulin requirements are less after total than after partial pancreatectomy or in many cases of diabetes. The reason for this is not known. Many samples of insulin contain a hyperglycemic substance which can be separated, and there is contradictory evidence that suggests that this substance may be secreted as a hormone by the α cells.

A pancreas grafted into the neck of a dog has been used to explore the mechanism of insulin secretion and has shown that this secretion is controlled mainly by humoral factors and to a lesser degree by nerve impulses. Insulin is secreted continuously, as shown by the fact the blood sugar begins to rise immediately after pancreatectomy (Fig. 197). Insulin secretion is regulated by the blood-sugar level; it increases in hyperglycemia and diminishes in hypoglycemia. Hyperglycemia apparently stimulates the nerve centers and causes insulin secre-

[1] Best, Haist, Campbell, Han, Ridout, Griffith, Marks and Young, Fraenkel-Conrat, Evans, Herring and Simpson.

[2] The insulin content of thyroid-fed animals has not been measured, but lesions of the β cells have been observed, and insulin secretion is diminished.

tion through the vagus nerves;[1] but the main effect is produced by the direct action of glucose on the pancreas. This is shown in the following experiment: Glucose is injected into the artery of a pancreatic graft or of the pancreas *in situ*, and the blood sugar in the general circulation falls, owing to an increase in the secretion of insulin[2] (Fig. 199).
FIG. 199. Direct effect of glucose on insulin secretion. The injection of 2.5 per cent glucose into the artery of a pancreatic graft provoked hypoglycemia (solid line); injection of Locke's solution did not have this effect (crosses); glucose injection in the jugular vein did not produce hypoglycemia (dashes). The horizontal bar represents the time of the injection; the ordinate, blood sugar in grams per cent. (*Foglia, V. G., and R. Fernández, Rev. Soc. argent. de biol., vol. 11, p. 556, 1935.*)

A pancreatic graft maintains a normal blood-sugar level in pancreatectomized dogs. The insulin secretion of the graft is so well controlled that a dog can have three pancreatic grafts beside its own pancreas and still have a normal blood-sugar level. When a pancreas is grafted into a diabetic dog the blood sugar falls to the normal level in 3 to 5 hr., and remains there. To obtain a similar blood-sugar curve by giving insulin to a diabetic animal, it is necessary to inject doses that diminish from 10 to 1 as the blood sugar falls to normal. All these facts demonstrate that insulin secretion controls the blood-sugar level, and reciprocally the blood-sugar level controls insulin secretion.

The extrinsic innervation of the pancreas plays a secondary part in the control of insulin secretion. A pancreatic graft has no nerves, yet it secretes insulin in the varying quantities needed to maintain the blood-sugar level normal and to control hyperglycemia when this occurs. The blood-sugar level is not altered by pancreatic denervation or section of the vagi, nor is the resynthesis of muscle glycogen disturbed. Reports of insulin secretion obtained by stimulating the vagi have been published,[1] but they have not been confirmed by others, in particular by the careful experiments of Etcheverry. Nevertheless the nervous system contributes to the regulation of pancreatic secretion, although it is not indispensable. After pancreatic denervation the return to a normal blood-sugar level following hyperglycemia or hypoglycemia is less rapid than in normal animals (Fig. 200). In the case of hyperglycemia the increase in insulin secretion is delayed; in the case of hypoglycemia inhibition of insulin secretion is delayed.

In all types of diabetes there is a deficiency in insulin secretion. This can be due to (*a*) lesions in the β cells or inhibition of the islets, causing a decrease in insulin secretion (absolute insufficiency); (*b*) resistance of the organism to insulin, although insulin secretion is normal or greater than normal (relative insufficiency).

The capacity of the pancreas to secrete insulin can be established by grafting it into the neck of a diabetic dog. A normal pancreas brings the blood sugar to a normal level in 3 to 5 hr. A pancreas that has had its mass considerably reduced surgically, or that has damaged islets as a result of previous treatment with anterior hypophysis, alloxan, or thyroid, either takes much longer to reestablish a normal blood-sugar level (diminished insulin secretion) or is incapable of controlling hyperglycemia (no insulin secretion).[2]

DIABETES

Symptoms and metabolic disturbances. Total pancreatectomy produces a diabetes of maximum severity. Pancreatic diabetes has a rapid course in the dog, in the cat, and in man,

[1] This fact, reported by Zunz and La Barre, was not confirmed by Gayet.

[2] Grafe and Meythaler, 1927; Gayet, 1928 to 1933; Foglia and Fernández, 1935.

[1] De Corral, Zunz, and La Barre, and others.

[2] Houssay and Foglia, 1936; Houssay, Foglia, Smyth, and De Finis, 1941 to 1943; Houssay, 1944.

but it progresses more slowly in the rat and in other species. The principal signs of diabetes are (*a*) *polyuria*, *i.e.*, an increase in the excretion of urine, a sign which was observed before sugar was discovered in the urine and which is the origin of the name given to the disease; (*b*) *polydipsia*, *i.e.*, increased ingestion of water caused by a strong sensation of thirst; (*c*) *polyphagia*, *i.e.*, increased ingestion of food, caused by a voracious appetite, in spite of which the subject loses weight and gradually becomes emaciated; (*d*) *hyperglycemia*, the blood sugar rising to 200 or 400 mg. per cent; (*e*) *glycosuria*, the urine containing 5 to 10 gm. per cent of glucose. Wounds are easily infected.[1] In severe diabetes there is a high metabolic rate, elimination of nitrogen in the urine increases, fat is rapidly lost, and finally the animals die in cachexia. Before the discovery of insulin the main cause of death of diabetic patients was diabetic coma due to acidosis.

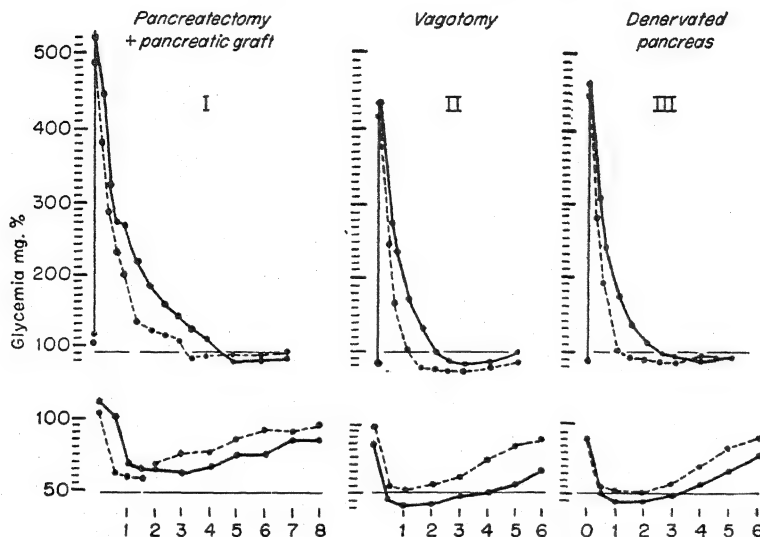
Liver glycogen is considerably diminished. Injection of glucose causes little increase in liver glycogen and in severe diabetes none at all. Muscle glycogen remains normal, but it can diminish in advanced diabetes. The fall in muscle glycogen caused by muscular contraction is similar to that observed in normal animals, but resynthesis of glycogen proceeds at a slower rate.


Fig. 200. Effect of pancreatic denervation on the recovery of the normal blood-sugar level. Above: average blood sugar of dogs after intravenous injection of 1 gm. glucose per kilogram. Below: average blood sugar of dogs after intravenous injection of 3 units insulin per kilogram. I: solid line, six pancreatectomized dogs with a pancreatic graft in the neck (chloralose anesthesia); broken line, six chloralosed controls. (*Houssay, Lewis, and Foglia, 1928–1929.*) II: solid line, 12 vagotomized dogs (without anesthesia); broken line, controls (no anesthesia). (*Etcheverry, 1937.*) III: solid line, six dogs with denervated pancreas (no anesthesia); broken line, controls (no anesthesia). (*Etcheverry, 1937.*)

It is remarkable that glycogen increases in the heart muscle and the leukocytes, and sometimes there are glycogen deposits in the renal tubes. The so-called "hydropic degeneration" of the β cells of the islets consists in deposition of glycogen in the protoplasm.

Administration of glucose has the following effects: (*a*) there is a high and prolonged hyperglycemia; (*b*) on the following day the urine contains the same amount of sugar as was injected, or more; (*c*) the RQ does not rise as in normal subjects. These three facts have been interpreted to mean the diabetic organism does not burn sugar. This is not so, because the eviscerated dog burns sugar, a process which, according to Soskin, takes place at a lower rate than the normal at the same blood-sugar levels. Isolated organs, *e.g.*, the heart, consume glucose, although at a lower rate than in normal conditions (Lovatt-Evans). Moreover, after removal of the anterior hypophysis, pancreatectomized

[1] Susceptibility to infection increases with the severity of hyperglycemia and diabetes; nevertheless it is not caused by the excess glucose, but apparently by protein metabolites (Menkin).

animals retain and utilize part of the sugar they receive (Houssay and Biasotti). Hédon has also found an increase in RQ in the final stages of pancreatic diabetes in the dog.

The RQ is approximately 0.7 in diabetics; this has suggested that the diabetic organism burns fat almost exclusively. This interpretation cannot be accepted as final because an RQ of 0.7 may be the result of two simultaneous processes that have opposite effects on the RQ, *i.e.*, oxidation of sugar with RQ = 1 and conversion of fat into sugar with RQ = 0.3.

Diabetic hyperglycemia is dependent on the liver, because it is not possible to provoke any type of diabetes (pancreatic, hypophyseal, etc.) if the liver has been removed. Hepatectomy in a diabetic animal causes the blood sugar to fall rapidly to a low level (Fig. 195), with the appearance of signs of severe hypoglycemia; the animal's condition is relieved by the injection of glucose. Both these facts are further proof that glucose can be utilized in the absence of insulin.

Proteins can give rise to glucose. This process takes place, or at least is begun, in the liver, because this organ is the main site of deamination of amino acids.

In the normal liver, glucose secretion diminishes or ceases when the blood sugar rises, but the diabetic liver has lost this homeostatic property and continues to pour sugar into the blood in spite of hyperglycemia (Soskin). A severely diabetic dog, when fasting, eliminates more sugar than can be accounted for by carbohydrate stored in the body. Urinary nitrogen increases, and the ratio of glucose to nitrogen in the urine (dextrose-nitrogen, D/N, or glucose-nitrogen, G/N, ratio) varies between 2.8 and 3.6. The G/N ratio is taken as an index of the amount of protein converted into glucose. Thus 1 gm. of N is the equivalent of 6.25 gm. of protein; therefore if for every gram of N in the urine there are 3.6 gm. of glucose, 60 per cent of the protein metabolized will have been converted into glucose, which is lost in the urine.[1]

Amino acids have been given to animals with pancreatic or phlorhizin diabetes. The following amino acids provoke the excretion of extra sugar in the urine: glycine, alanine, serine, threonine, valine, glutamic and aspartic acids, ornithine, proline, arginine, cystine, and methionine; they are known as glycogenic amino acids.[1] Other amino acids do not increase urinary glucose, but cause a rise in urinary ketone bodies. The ketogenic amino acids are the following: phenylalanine, tyrosine, leucine, isoleucine, and valine.

An important metabolic disturbance in diabetes is the decrease in the conversion of sugar into fatty acids, catalyzed normally by insulin, to 5 per cent of the normal figure (Stetten).

In severe diabetes fat consumption increases considerably. The greater mobilization of fats causes increased lipemia (to 5 or 10 per cent or even more). Blood cholesterol also rises. The liver has a yellowish color, due to fatty infiltration. Glycerol (10 per cent of fat) is readily converted into glucose. Palmitic acid can also be converted into glucose in the pancreatectomized dog.

In the course of fat metabolism ketone bodies (β-hydroxybutyric acid, acetoacetic acid, and acetone) are produced in the liver and afterward burned in the tissues. When large quantities of fats are metabolized an excess of ketone bodies is produced. Some of them are not burned and they accumulate in the blood (hyperketonemia) and pass out into the urine (ketonuria). In the bladder and in the lung, acetoacetic acid is partially converted into acetone, giving off CO_2, and the breath and urine have the peculiar smell of acetone. β-Hydroxybutyric acid is the most abundant of the ketone bodies. Acetoacetic acid is more toxic, because of its enolic function.[2] Accumulation of these acids causes acidosis. The alkali reserve diminishes, pulmonary ventilation increases, alveolar CO_2 tension falls, urinary ammonia increases, and the pH remains normal (compensated acidosis) or falls (uncompensated acidosis).

Diabetic coma is the outcome of acidosis. At first there is headache, then mental torpor, and finally loss of consciousness. There are nausea and vomiting; abdominal pain and constipation; air hunger, with deep inspirations (Kussmaul breathing); elimination

[1] This ratio is not as constant as it was thought to be. Drury (*J. Clin. Investigation,* **21,** 153, 1942) maintains that the true G/N ratio is from 5 to 7, but that part of the glucose formed is burned; thus the ratio appears to be only 2.8.

[1] According to Bancroft and Drury (*Am. J. Physiol.,* **166,** 213, 1951), if glucose formed and oxidized is taken into account, 90 to 95 per cent of protein can be converted into glucose, and all amino acids would be glycogenic.

[2] Acetoacetic acid has a ketonic $CH_3 \cdot CO \cdot CH_2 \cdot COOH$ and an enolic $CH_3 \cdot COH{=}CH \cdot COOH$ form.

of acetoacetic acid in the urine, which smells of acetone; acidosis (alkali reserve below 25); anhydremia, frequently hypochloremia and increase in nonprotein nitrogen in the blood. There is also a gradual fall in blood pressure. Diabetic coma is treated by the injection of insulin; anhydremia, by intravenous injection of saline solution with or without glucose; and acidosis, by the administration of sodium bicarbonate. Circulatory disturbances should be treated, the stomach should be washed out, and the patient should be kept quiet and warm.

Endocrine pancreatic insufficiency in human diabetes is often slight or moderate in degree, but the severest forms are also observed. In prolonged human diabetes vascular lesions are common. There may be arteriosclerosis with occlusion of the blood vessels, causing gangrene in the limbs, occlusion of the coronary arteries, and lesions in the retina. In some cases the crystalline lens of the eye becomes opaque (diabetic cataract).

Insulin treatment controls nearly all the effects of diabetes. Glucose consumption by the tissues is increased, the excess consumption of fat and protein ceases, liver and muscle glycogen return to normal, hyperlipemia retrogresses, ketosis disappears, and the alkali reserve increases. Each injection of insulin has a marked but only transitory effect, so that repeated doses must be given. A more prolonged effect on the blood sugar, with a more nearly normal blood sugar, can be obtained by injecting insulin preparations that are reabsorbed slowly, such as crystallized insulin, zinc insulin (Scott and Fisher), protamine insulin, protamine-zinc insulin, histone insulin, globin insulin, etc. Protamine insulin[1] is a combination of the two proteins, which flocculate when brought together and then slowly dissociate. This type of insulin has the following advantages: (*a*) the effect is prolonged; (*b*) the glycemic curve is nearer to the normal; (*c*) a smaller number of injections are needed; (*d*) acidosis is more easily controlled; (*e*) hypoglycemic accidents are less frequent. The greater part of insulin used in the treatment of diabetics is protamine insulin, especially NPH 50.

Fortunately insulin is a protein that does not provoke the formation of antibodies, so it continues to produce effects in spite of being injected daily for many years. Resistance to insulin owing to antibody formation has been observed in exceptional cases. Allergic hypersensitiveness to insulin is also exceptional.

[1] Prepared and studied by Hagedorn, Jensen, Krarup, Woodstrup, etc.

Insulin increases activity and prolongs life in diabetic patients. It also permits the survival of patients with juvenile diabetes—a severe, almost certainly fatal, form in the preinsulin era. Death in diabetic coma is now seldom observed.

Hypoglycemia

Causes. The quickest way to produce hypoglycemia is to inject a large dose of insulin. In the rat and rabbit, when the blood sugar falls below 50 mg. per cent, signs of hypoglycemia are observed. Glucose injections are followed by a spectacular recovery from insulin hypoglycemia; within a few minutes all signs of it disappear. Hepatectomy also provokes hypoglycemia, which is equally rapidly controlled by glucose injections. If hypoglycemia is prolonged, the recovery following glucose injections is not so rapid, nor so complete, because of permanent lesions in the nerve centers. These are due to the fact that glucose is the main source of energy of nerve cells.

The causes of hypoglycemia can be classified as follows:

1. Diminished ingestion of sugar: fasting, inanition, cachexia.
2. Deficient absorption of sugar: vomiting, pyloric stenosis, diarrhea.
3. Deficient hepatic homeostasis: hepatectomy, diseases causing extensive damage to the liver, von Gierke's disease.[1]
4. Deficient hepatic homeostasis of endocrine origin: hypophyseal or adrenal insufficiency, occasionally cachexia of hypothyroidism or hyperthyroidism.
5. Hyperinsulinism, *i.e.*, uncontrolled excess insulin secretion.
6. Excess glucose consumption: violent exercise, *e.g.*, marathon races.
7. Excess loss of glucose: renal glycosuria (rare), intense lactation.

Signs. There are many signs and symptoms of hypoglycemia. The following are the most commonly observed: (*a*) flushing of the skin with abundant sweating, or paleness and the sensation of

[1] There is an enlarged liver, with a high glycogen content; glycogen is not readily mobilized and there is hypoglycemia and ketosis. The disease is also called glycogenosis or glycogenic thesaurismosis.

cold; (*b*) palpitations; (*c*) hunger, yawning, epigastric pain, nausea; (*d*) weakness, tiredness, apathy, dizziness; (*e*) anxiety, nervous excitement, aggressiveness, symptoms similar to drunkenness; (*f*) difficulty in performing movements or in speech, tremor, spasms, diplopia; (*g*) convulsions; (*h*) psychic disturbances such as emotional instability, difficulty in concentration, absent-mindedness, disorientation, mental confusion, delirium, amnesia, etc.; (*i*) loss of consciousness, coma. Death may occur if adequate treatment is not given.

Hypoglycemia is treated by giving glucose, fructose, or mannose by mouth. In cases of emergency, glucose should be injected intravenously. Adrenaline and pituitrin are also used, but they are less efficient.

Hypoglycemia and coma (insulin shock) have been provoked deliberately for the treatment of certain mental conditions, *e.g.*, schizophrenia (Sakel's treatment).

Hyperinsulinism is a rare disease in which the pancreas secretes an excess of insulin.[1] Hypoglycemia that occurs on fasting or a few hours after a meal is easily controlled by the ingestion of sugar.

Hypoglycemia is also observed in cases of islet adenoma; extirpation of the adenoma cures the patient.

Insulin treatment has been given with the object of fattening thin persons. The insulin hypoglycemia stimulates the nerve centers of the vagus, thus provoking gastric contractions and secretion, and therefore hunger.[2] Not only does the patient eat more, but the conversion of carbohydrate into fat is also increased.

The Role of the Hypophysis

In acromegaly—a disease due to excess function of the anterior hypophysis—hyperglycemia, glycosuria, and diabetes are frequently found (according to Atkinson in 32.8 per cent of 817 cases collected in the medical literature).[3] This fact had been well known for many years, but the importance of the anterior hypophysis in carbohydrate metabolism has been demonstrated much more recently.

Hypophysectomy. Total hypophysectomy causes many and varied disturbances in carbohydrate metabolism, which are also observed

[1] Harris, 1923; Wilder, 1927.

[2] Bulatao and Cannon.

[3] Atkinson, P. R. B., *Endokrinologie*, **66**, 332, 1938.

after removal of the anterior lobe (pars distalis), but not after that of the posterior lobe.

1. Intestinal absorption of sugar is slowed down,[1] therefore the sugar-tolerance glycemic curve is flattened.
2. After a meal the blood sugar and liver glycogen are normal, but they fall rapidly during fasting[2] and severe hypoglycemia occurs.[3] If treatment by the administration of sugar is not given soon, the subjects die. Hypoglycemia can be prevented by feeding a diet rich in carbohydrate or protein, but not by an exclusively fat diet. Administration of anterior hypophysis or corticoadrenal hormones prevents these accidents. The capacity to maintain a normal blood-sugar level and normal glycogen concentration, to increase muscle glycogen and to control excessive glucose consumption is called by Russell the "glycostatic" function of the anterior hypophysis.
3. Hypophysectomized animals, and those in which the anterior lobe only has been removed, are very sensitive to the hypoglycemic effect of insulin.[4] Small doses of insulin, which have no effect in normal controls, provoke intense hypoglycemia, convulsions, and death. The animals that recover do not regain a normal blood sugar for several hours. There is also increased sensitiveness to other hypoglycemic agents, such as phlorhizin.[5] Loss of hypophyseal growth hormone and adrenal insufficiency contribute to establish this hypersensitiveness. Treatment with anterior hypophysis not only corrects this hypersensitiveness but provokes insulin resistance.[6] Young has called this tne "glycotropic" effect of the anterior hypophysis.
4. Extirpation of the hypophysis, or of its anterior lobe (pars distalis), is followed by marked attenuation of pancreatic and phlorhizin diabetes.[7] Houssay and Biasotti's

[1] Phillips and Robb, 1934. This fact has been amply confirmed.

[2] Houssay and Biasotti, 1930; Russell, Cope, etc.

* The slight attenuation of diabetes observed in craneotomized animals, more marked in those with lesions in the tuber, is due to disturbances in the circulation of the hypophysis provoked by these operations, which cause damage and hypofunction of the pars distalis.

strated the "diabetogenic" effect of the anterior hypophysis, its presence increasing the severity of diabetes, while its removal attenuates it. In the toad the diabetogenic effect is produced also after removal of the forebrain or diencephalon, the digestive tract, the lung, the kidneys, or the following endocrine glands: adrenals, thyroid, or gonads. It is not observed after removal of the liver.[1] A diabetogenic activity has been found in the anterior hypophysis of fishes, amphibians, reptiles, birds, and mammals. The anterior hypophysis of man has a particularly strong diabetogenic activity.

In mammals, including man, hypophysectomy also attentuates the severity of pancreatic diabetes (Table 43). The same effect is produced by the removal of the anterior, but not of the posterior, lobe. Comparing hypophysopancreatectomized dogs with pancreatectomized dogs, it is seen that hyperglycemia is not so marked and that the blood sugar rises less after the ingestion of food. There is less glycosuria, less elimination of urinary nitrogen, and the G/N ratio is lower. This decrease in protein break-

* Figures in parentheses are the extreme values.

(1930) experiments showed that in the toad total hypophysectomy or extirpation of the pars distalis diminished the rise in blood sugar and prevented glycosuria caused by pancreatectomy (Table 42). Implantation of the pars distalis, on the contrary, increased the severity of diabetes to its previous degree or even more. This experiment demon-

down suggests that conversion of protein into sugar is also diminished. Survival is more prolonged, and body weight is lost at a much slower rate. There is less elimination of ketone bodies,[2] probably because of a lesser breakdown of fat. The administration of glucose causes a rise in

[1] Campos, Curutchet, and Lanari, 1933; Foglia, 1942.
[2] Rietti, 1930; Long and Lukens, 1936.

the RQ; glucose is sometimes completely consumed, but usually only in part. It is evident that these animals consume glucose, but at a lower rate than normal animals (Chambers). Slices of surviving tissues taken from these animals consume glucose at a higher rate than the tissues of pancreatectomized animals, but a lower one than the tissues of normal controls. Fasting causes a rapid fall in blood sugar, with signs of severe and even fatal hypoglycemia, which is easily controlled by the administration of glucose.

During the fall in blood sugar, glucose oxidation increases in the hypophysectomized rat (Russell) and rabbit (Greeley), but not in the dog.[1] The fall in blood sugar has been attributed to excessive glucose consumption, but it is due mainly to a disturbance in the function of the liver, which does not increase the secretion of glucose into the blood while the blood sugar is falling, as occurs in normal animals.[2] The relative importance of the two mechanisms is still a moot point. Some workers (Cori, Russell) consider the lack of a moderating action of the hypophysis on glucose consumption to be the most important cause; others consider that the liver does not secrete enough glucose during fasting or when there is hypoglycemia.

The diabetogenic effect of hypophyseal extract. Injection of extracts of the pars distalis of the hypophysis compensates for the effects of hypophysectomy on carbohydrate metabolism, and large doses provoke the appearance of signs opposite to those of hypofunction. This treatment increases the severity of the attenuated pancreatic diabetes in hypophysectomized animals and of diabetes in pancreatectomized animals; also it provokes diabetes in normal mammals.[3] The dose of extract necessary to produce the diabetogenic effect decreases in proportion to the amount of pancreatic tissue extirpated.

Daily intraperitoneal injections of anterior hypophyseal extracts produce in dogs, after 2 to 4 days, a diabetic state (hypophyseal diabetes) with the following characteristics: (*a*) there is a latent period before the appearance of diabetic symptoms; (*b*) there are hyperglycemia, glycosuria, ketonuria, hyperlipemia, and a fatty liver; (*c*) there is marked insulin resistance; (*d*) there is a high liver-glycogen content, except when there is considerable hyperglycemia; (*e*) insulin secretion diminishes 2 to 3 days after the onset of hyperglycemia,[1] and the insulin content of the pancreas also decreases;[2] (*f*) glucose injection is followed by a "diabetic" blood-sugar curve, and there is little or no increase in the RQ;[3] (*g*) hyperglycemia and glycosuria are not observed if the animal is kept fasting or on an exclusively fat diet, but they are observed when the animal is fed a protein diet, and with greater facility if a carbohydrate diet is given; (*h*) the dog is very sensitive to the diabetogenic effect, the rat less, and to obtain it in the toad partial pancreatectomy must be previously performed; (*i*) the smaller the mass of pancreatic tissue remaining in the organism, the easier it is to provoke hypophyseal diabetes; (*j*) hepatectomy causes the blood sugar to fall in animals with hypophyseal diabetes, and this cannot be provoked if the liver has been previously removed.

The growth hormone of the hypophysis has a potent diabetogenic effect and produces transient (Cotes and Young) or permanent (Houssay and Anderson) diabetes. ACTH (adrenocorticotrophic hormone) also has a diabetogenic effect, but it is less potent. None of the other purified hormones has shown this property.

Severe hypophyseal diabetes can be provoked in animals after removal of the hypophysis and the pancreas; therefore it is caused by an extrapancreatic mechanism. In animals with pancreatic tissue the blood sugar rises and there is insulin resistance 2 to 3 days before lesions are observed in the β cells, and insulin secretion diminishes. The damage in the islets is due to (*a*) hyperglycemia; (*b*) a toxic effect of the hypophyseal extract. Hyperglycemia alone is not responsible for these lesions, since they are not observed in animals in which the blood sugar is maintained for several days at the same high level as in hypophyseal diabetes; neither does the effect of insulin diminish in these animals.

During the first few days hypophyseal diabetes can be prevented or cured by insulin treatment (Lukens). If the hypophyseal injections are dis-

[3] Biasotti, 1934.

continued the diabetic condition disappears in a few days; also if the dose of extract is not gradually increased it may become inefficacious after 8 or 10 days' treatment. If, on the contrary, the hypophyseal diabetic state is maintained for a sufficiently long time, it persists even after hypophyseal treatment is discontinued, and the animal remains with a permanent diabetes. This was first obtained in dogs with partial pancreatectomy (Houssay, Biasotti, and Rietti, 1932) and later in animals with an intact pancreas (Young, 1937). Transitory diabetes observed during hypophyseal treatment is called hypophyseal diabetes (Houssay) or idiohypophyseal diabetes. Permanent diabetes that persists after hypophyseal treatment is discontinued is called metahypophyseal diabetes (Houssay).

Histologic examination of the pancreas made on successive days during anterior hypophyseal treatment shows progressively increasing damage to the β cells.[1] First the cells lose their granulation and there is hydropic degeneration. These lesions are reversible and can be cured spontaneously or by insulin treatment.[2] In this stage insulin secretion and insulin content in the pancreas are diminished. Later the β cells degenerate and disappear; the islets suffer hyaline degeneration and atrophy. At this stage the animal has acquired a permanent diabetes, which is simply a pancreatic diabetes due to insufficiency of β cells in the islets; the exocrine pancreas remains undamaged. In idiohypophyseal diabetes—caused and maintained by anterior hypophyseal extract—there is insulin resistance; metahypophyseal diabetes is due to β cell insufficiency, caused by permanent damage to these cells produced by the injection of anterior hypophyseal extract, which is now no longer necessary to maintain the diabetic state.[3]

Other effects of anterior hypophyseal extract. Anterior hypophyseal extract can stimulate the endocrine pancreas and produce hypertrophy and hyperplasia of the islets,[4] with increased insulin secretion and insulin content in the pancreas.[1] This effect has been attributed to a pancreatotrophic hormone, the existence of which has not been demonstrated. The anterior hypophysis is not necessary for the development and maintenance of the islets; hypophysectomy diminishes growth of the islets (Haist), but it has a more marked effect on the acini, so there is a relative increase in islet tissue, although the total amount is below normal. Insulin content of the pancreas and insulin secretion are not modified by hypophysectomy in the dog.

Certain hypophyseal extracts lower the blood sugar in fasting rabbits and rats, and in man.

The mechanism of the anterior hypophyseal diabetogenic effect. According to Cori and his associates anterior hypophyseal extract inhibits hexokinase *in vitro* and *in vivo;* insulin would antagonize this inhibitory effect. The opposite action of the hormones on the enzyme explains many of the facts, but not all; *e.g.*, it gives no satisfactory explanation of the hypersensitiveness to insulin of hypophysectomized animals. Moreover, purified growth hormone has a potent diabetogenic effect, but does not antagonize hexokinase.

The anterior hypophysis apparently controls carbohydrate consumption and the secretion of glucose by the liver. It stimulates the mobilization and metabolism of fat and the conversion of carbohydrate into fat (see Chap. 42); it increases the formation of protein during growth, and protein breakdown in severe diabetes (see Chap. 43).

The posterior hypophysis. Removal of the posterior lobe does not modify the blood-sugar level, the sensitiveness to insulin, or the course of diabetes. Transitory hyperglycemia is provoked by large doses of posterior hypophyseal extract, which acts on the liver, increasing glucose secretion. Adrenaline increases sensitiveness to this hyperglycemic effect.[2] Posterior hypophyseal extract increases slightly the blood sugar of toads after removal of the pancreas and the hypophysis, but it does not provoke diabetes even in partially pancreatectomized animals.

The Role of the Adrenals

The adrenal cortex. The adrenal cortex plays an important part in carbohydrate, fat, and protein metabolism. Metabolic disturbances observed in adrenal insufficiency are similar to

[1] Richardson and Young, 1938; Richardson, 1940; Porto, 1941.

[2] Lukens and Dohan, 1942.

[3] In some cases of acromegaly there is diabetes with insulin resistance; in others the response to insulin is normal. Probably the former are suffering from hypophyseal diabetes and the latter from metahypophyseal diabetes.

[4] Anselmino and Hoffmann, 1933; Marks and Young, 1939 and 1940.

[1] Houssay, Foglia, Smyth, and Houssay.

[2] Borchardt, 1908; Houssay and Di Benedetto, 1933.

those seen in hypophyseal insufficiency. In adrenalectomized animals and patients with Addison's disease, the blood sugar and liver glycogen fall rapidly after a few hours' fasting. Glucose administration at first restores the normal blood-sugar level and liver glycogen content. As adrenal insufficiency advances, the capacity to form glycogen from injected glucose diminishes first in the liver and later in the muscles; resynthesis of muscle glycogen after fatigue is also retarded (Fig. 198). Previous treatment with corticoadrenal extract prevents the fall in blood sugar and glycogen in fasting adrenalectomized or hypophysectomized animals, and increases the storage of glycogen after glucose administration. Adrenalectomized animals are easily fatigued. Their performance can be improved by the administration of glucose, and much more so by treatment with certain corticoadrenal hormones (Ingle). They fall readily into hypoglycemia when food is withheld or when they are given drugs which provoke hypoglycemia, *e.g.*, insulin,[1] phlorhizin, etc., and when the blood sugar decreases following hyperglycemia provoked by injection of glucose. This hypersensitiveness to insulin is suppressed by factors which in large doses cause insulin resistance in normal and in hypophysectomized dogs: (*a*) adrenocortical extract and glucocorticoids of the adrenal cortex; (*b*) adrenocorticotrophin when the adrenal cortex functions. Desoxycorticosterone and the administration of sodium chloride do not have this effect.

Adrenalectomy diminishes considerably the severity of pancreatic and phlorhizin diabetes, a fact well demonstrated in the cat by Long and Lukens[2] and confirmed in other species[3] (Table 43). Hyperglycemia, glycosuria, ketonuria, urinary nitrogen, and the G/N ratio diminish. Diabetes again becomes severe in adrenalectomized rats when the corticoadrenal tissue is regenerated. In adrenalectomized dogs and cats treatment with corticoadrenal extract or glucocorticoids, but not with sodium chloride, increases the severity of diabetes. Diabetic patients also show a diminished severity in their disease if adrenal insufficiency is established owing to Addison's disease or surgical removal of the adrenals (Thorn, Sprague).

The corticoadrenal hormones with the greatest activity in carbohydrate metabolism have oxygen in an alcoholic or ketonic group in C^{11}. Among the most active are 11-dehydrocorticosterone, 11-dehydro-17-hydroxycorticosterone, and corticosterone; desoxycorticosterone is much less active. These hormones are active in animals and man (Thorn). Large doses (10 mg. per day) produce hyperglycemia and glycosuria in pancreatectomized and normal rats (steroid diabetes, Ingle). They increase liver and muscle glycogen, protein breakdown, and the severity of pancreatic and phlorhizin diabetes which has been attenuated by adrenalectomy or hypophysectomy; also they have an antagonistic action to insulin.

Daily injections of large doses of adrenocorticotrophin in man produce signs of diabetes, such as glycosuria, moderate hyperglycemia, and decreased reabsorption of glucose in the renal tubes. There is also an increase in uric acid excretion and sometimes in the output of nitrogen.[1] So far, permanent diabetes has not been provoked by treatment with corticoadrenal hormones. Nevertheless diabetes has been observed in many patients with adrenocorticoadenoma, and in some cases extirpation of the adrenal tumor has cured the diabetes. A diminished glucose tolerance and transitory diabetes have also been observed in patients suffering from hyperfunction of the adrenal cortex (Cushing's disease, Achard-Thiers syndrome).

Some of the abnormalities in carbohydrate metabolism provoked by adrenalectomy are due to disturbances in sodium, potassium, and water metabolism. The ingestion of NaCl reestablishes the normal rate of glucose absorption which is diminished in adrenalectomized animals. On the other hand, sodium chloride does not prevent hypoglycemia in fasting adrenalectomized animals, nor does it increase the severity of pancreatic diabetes that has been attenuated by adrenalectomy or hypophysectomy. In these cases only corticoadrenal hormones, or substances similar to these hormones, are active.

According to Long the corticoadrenal secre-

[1] This fact has been observed in cats (Cannon), rats (Lewis), and dogs (Lewis and Magenta) and in patients suffering from Addison's disease (Marañon). They are, however, less sensitive than hypophysectomized animals (Bodo, 1952).

[2] Long, C. N. H., and F. Lukens, *J. Exper. Med.*, **63**, 465, 1936.

[3] Lukens in the dog; Hartman and Brownell in the cat; Long in the rat; and Houssay and Biasotti in the toad.

[1] Conn, J. W., *et al.*, *J. Lab. & Clin. Med.*, **33**, 651, 1948: **34**, 255 1949.

tion increases protein breakdown and the formation of sugar from protein. Adrenalectomized animals eliminate less urinary nitrogen in the fasting condition, and less nitrogen and glucose in the diabetic conditions caused by pancreatectomy or phlorhizin. Anoxia increases the elimination of nitrogen and the storage of glycogen in normal fasting rats, but not after adrenalectomy.

Corticoadrenal hormones not only increase glyconeogenesis, but also diminish glucose consumption by the tissues (Ingle) and, probably, the conversion of glucose into fat.

The adrenals are not indispensable for the production of hypophyseal diabetes,[1] but adrenal hormones assist in its development. The anterohypophysis provokes diabetes in two ways: (*a*) by the diabetogenic effect of the growth hormone without the intervention of the adrenals; and (*b*) by stimulation of the adrenal cortex through the adrenocorticotrophic hormone (Long).

The adrenal medulla. Adrenaline injections rapidly provoke hyperglycemia, and muscle- and liver-glycogen breakdown (see page 427, "Role of the nervous system"). While hyperglycemia lasts, glucose is burned in the tissues, but in some experiments a relative decrease in glucose oxidation has been reported. In some animals muscle glycogen is broken down to lactic acid which is reconverted into glycogen in the liver (Cori's cycle). The adrenal medulla secretes continuously a small amount of adrenaline, which does not seem to be of any importance in normal conditions, because removal of the adrenal medulla does not modify the blood-sugar level, nor does it change the course of pancreatic[2] or phlorhizin diabetes. Extirpation of the adrenal medulla, on the other hand, suppresses hyperglycemia produced by a sudden increase in adrenaline secretion (see Chap. 85). Also, recovery of the normal blood-sugar level after insulin is significantly retarded when adrenaline secretion has been suppressed.[3]

The Role of the Thyroid

The internal secretion of the thyroid increases the rate of intestinal absorption of glucose and especially of galactose. In thyroid and anterior hypophyseal insufficiencies absorption of sugar is slow, and in both cases treatment with thyroid or thyroxin improves sugar absorption. In experimental hyperthyroidism sugar is absorbed more quickly than in normal controls. In pa-
FIG. 201. Blood-sugar curves (average of 11 cases) after ingestion of 1.75 gm. glucose per kilogram while fasting. Solid line, hyperthyroid subjects before operation; average BMR 62 ± 17. Broken line, the same subjects after thyroidectomy; average BMR 3 ± 3.3. Before operation the RQ rose from 0.74 to 0.97, and after operation from 0.78 to 0.99. Before operation 38.4 per cent of the glucose ingested was consumed, and 19.4 per cent after operation. (*Yriart, M., and H. Gotta, Rev. Soc. argent. de biol., vol. 6, p. 1604, 1932.*)

tients with hyperthyroidism increased velocity of absorption has also been observed; after ingestion of glucose (Fig. 201) or galactose (Fig. 202) the blood-sugar curve rises to higher levels than in normal subjects.[1] Intravenous injection of galactose produces the same type of glycemic curve in normal and hyperthyroid subjects. After extensive thyroidectomy—sufficient to control hyperthyroid symptoms—normal postabsorptive glucose and galactose blood-sugar curves are obtained.

In cases of hyperthyroidism the fasting blood sugar is normal, or occasionally a little above normal (120 to 140 mg. per cent); in 15 to 60 per cent slight glycosuria is found, especially after meals. A diagnosis of diabetes should therefore not be made in a hyperthyroid patient unless the fasting blood sugar is above 150 mg. per cent and the blood sugar tolerance curve rises

[1] ALTHAUSEN, T. L., *J. A. M. A.*, 115, 101, 1940; "Essays in Biology in Honor of Professor H. M. Evans," University of California Press, Berkeley, 1943, p. 13.

above 200 mg. per cent; in nonhyperthyroid subjects a fasting blood sugar of 130 mg. per cent and a sugar-tolerance curve that rises to 180 mg. per cent are considered signs of diabetes.

Sensitiveness to insulin is usually increased in thyroidectomized animals[1] and in many cases of severe myxedema; in hyperthyroidism insulin resistance is frequently increased.

Fig. 202. Galactose-tolerance curves. Average figures of 97 subjects with no thyroid disease (solid line) and of 130 subjects with hyperthyroidism (broken line). (*Althausen, T. L., J. A. M. A., vol. 115, p. 101, 1940.*)

In hyperthyroidism liver glycogen, then heart glycogen, and finally muscle glycogen are considerably decreased. In an advanced stage there is hypoglycemia and hypersensitiveness to insulin. The effect of the thyroid on liver glycogen is antagonized by vitamins A, B, and C, yeast, some fats, and a protein diet.

The endocrine pancreas is stimulated in some animals by thyroid treatment (hypertrophy of the islets and increase in insulin content). Prolonged thyroid treatment, even with large doses, does not seem to cause damage to the normal pancreas; but in dogs with a pancreas reduced by ample surgical extirpation, or by previous treatment with anterior hypophysis, thyroid treatment damages the β cells and the animals become diabetic (thyroid diabetes). If the treatment is not prolonged, the β cells recover and the animal returns to normal, but if it lasts a sufficiently long time the islet lesions become irreversible and permanent diabetes results, which persists even when thyroid administration is discontinued (metathyroid diabetes).[1]

The diabetogenic activity of the thyroid is less intense than that of the hypophysis or the adrenal; nevertheless diabetes occurs twice as frequently in hyperthyroid patients (John) and three times more frequently in patients with adenomatous goiter than in subjects without goiter (Wilder). Diabetes does not provoke hyperthyroidism, which is not more frequent in diabetic subjects than in the general population; but diabetes and hyperthyroidism act reciprocally, each condition increasing the severity of the other. These patients need careful treatment, especially of the hyperthyroid state. Ample thyroidectomy permits the treatment of diabetes as successfully as in nongoitrous subjects. Survival is prolonged; hyperglycemia, glycosuria, and acidosis diminish; and a smaller daily dose of insulin is needed to maintain a normal blood sugar.

Thyroidectomy does not modify the course of pancreatic diabetes in the dog[2] and cat,[3] but it has a marked preventive effect on diabetes provoked by total pancreatectomy in the rat.[4] Thyroidectomy has been performed in diabetic patients who had no thyroid disturbance; carbohydrate tolerance increased and insulin requirement diminished in these patients, but diabetes was not cured. Cases of thyroid insufficiency in diabetics have been reported in which improvement and apparently complete disappearance of the diabetic condition was observed, but the sugar-tolerance curves were still of the diabetic type. Thyroidectomy should not be performed in uncomplicated cases of diabetes to improve carbohydrate metabolism, because it provokes myxedema, which does not add to the patient's comfort, and diabetes can be efficiently treated by other means.

The Role of the Gonads

The incidence of diabetes following removal of 95 per cent of the pancreas in rats is much higher in males than in females. Castration increases incidence of diabetes in subtotally pancreatectomized female rats.[5]

Estrogens administered over long periods have a marked protective effect against diabetes in subtotally pancreatectomized male and female castrated rats. Androgens, on the contrary, increase the severity of diabetes and shorten the period of survival after subtotal pancreatectomy.[1] Estrogens cause hyperplasia of the pancreatic islets and inhibit the hypophysis. In rats diabetes has been cured by treatment with estrogens and insulin. Diabetes is more frequently observed in women than in men (Joslin, Marks).

FIG. 203. Regulation of blood-sugar level. Sympathicoadrenohepatic mechanism on the right and vagus-insulin mechanism on the left.

ROLE OF THE NERVOUS SYSTEM

The nervous system assists in the regulation of the blood-sugar level together with the more important humoral factors. Impulses arising in the nerve centers are discharged along two peripheral paths, which modify the blood sugar in opposite directions: (*a*) the sympathicoadrenal-hepatic path, which increases hepatic glycogenolysis and provokes transitory hyperglycemia; (*b*) the vagus-insulin path, which provokes hypoglycemia (Fig. 203). According to the circumstances one of the two mechanisms prevails; usually the sympathicoadrenal is the more active of the two. The suppression of one by section of the corresponding nerves or extirpation of the gland (adrenal or pancreas) leaves the other without its antagonist, and its effects can be more easily demonstrated.

Peripheral stimulation of the splanchnic nerve brings the sympathicoadrenal mechanism into activity. The stimulus spreads along two paths: (*a*) along the hepatic nerves to the liver, where sympathin is set free, provoking glycogenolysis, increased secretion of glucose by the liver, and a rise in blood sugar; (*b*) along the adrenal nerves to the adrenal medulla, provoking secretion of adrenaline, which is carried by the circulation to the liver, where it provokes glycogenolysis, secretion of sugar into the blood, and hyperglycemia. In both cases the sympathetic acts through a chemical mediator: sympathin, which acts locally where it is liberated, or adrenaline, which passes into the general circulation and acts diffusely. Section of the splanchnic nerves suppresses both these paths; section of the liver nerves suppresses the direct (sympathin) effect on the liver, but the adrenal medulla remains active; denervation of the adrenal or extirpation of the adrenal medulla suppresses the effect of adrenaline, but the direct effect (sympathin) remains active (Fig. 203).

Intravenous injection of adrenaline breaks down liver and muscle glycogen. Other drugs provoke this effect indirectly by stimulating adrenal secretion; thus nicotine stimulates the adrenal medulla directly (denervation of the adrenal does not suppress its activity), and adrenaline causes glycogenolysis and hyperglycemia.

[1] LEWIS, J. T., V. G. FOGLIA, and R. R. RODRÍGUEZ, *Endocrinology*, **46**, 11, 1950.

Diffuse stimulation of the nerve centers spreads along both the sympathetic and the vagus nerve paths. Usually the effect of the former predominates and hyperglycemia results. Vagus-insulin activity is made evident by previously cutting both splanchnics or removing the adrenals, in which case hypoglycemia results.

Hyperglycemia due to stimulation of the nerve centers is observed in the following conditions: (*a*) emotion, anesthesia, stimulation of sensory nerves; (*b*) stimulation of the hypothalamus; (*c*) section at the level of the anterior colliculi; (*d*) section of the nerve stem at several levels, principally at the pons in the rabbit (Donhoffer and MacLeod); (*e*) piqûre (stimulation) of the floor of the fourth ventricle, mistakenly called diabetic piqûre by Claude Bernard;[1] (*f*) stimulation of the medulla or the spinal cord.

The effects of stimulation of the vagus have been considered in the paragraphs on insulin secretion.

The nervous, or neurohumoral, mechanisms that regulate the blood sugar are accessory to the more important humoral mechanisms. They are not indispensable, because the blood-sugar level does not change after section of the splanchnic or vagus nerves or after extirpation of the adrenal medulla. These operations do not change the course of experimental diabetes. The nervous mechanisms become active in situations of emergency, such as hypoglycemia, rage, fear, stimulation of the nerve centers, etc. In these circumstances they contribute significantly toward the increase of blood sugar.

Stimulation of efferent nerves does not have a direct effect on the blood sugar, but there is an increase in the glucose consumption of the muscles and glands innervated by the stimulated nerves. In muscular contraction glycogen is broken down and lactic acid produced.

METABOLIC SIGNIFICANCE OF CARBOHYDRATES

Carbohydrate food is the most readily available and cheapest source of energy that can be utilized by man. Approximately 500 gm. can be stored by the human body. This amount covers the need of only one day; therefore it must be given in the form of carbohydrate food or produced from other foodstuffs or body stores. Protein and fat stores are far more important than the meager carbohydrate store which is the equivalent of about 2000 kg.-cal. Carbohydrates "spare" protein, and when they are available less protein is catabolized; this is especially evident in protein fasting, *i.e.*, when there is no protein in the food ingested. Carbohydrates are easily converted into fat. When there is no carbohydrate available, either because the diet is deficient in this type of food or because the body cannot metabolize it (diabetes), more fat is catabolized and large amounts of ketonic bodies are formed (ketosis) which are excreted in part but are also accumulated in the organism, provoking acidosis. Carbohydrate is the principal source of energy mobilized in the course of muscular exercise.

CHAPTER 42

Fat Metabolism

The body lipids. Fats, or lipids, are found in living organisms and in organic foodstuffs. They are compounds of fatty acids and other substances. The main properties of fats are (*a*) they have fatty acids in their molecule; (*b*) they are insoluble in water and soluble in organic solvents (ether, chloroform, benzene, etc.); (*c*) they are utilized as foodstuffs by living organisms.

Fatty acids. Fatty acids with a carbon chain up to C_4 (butyric acid) are soluble in water. Up to C_{10} they are volatile, and up to C_{11} they are liquid at room temperature. When the chain has C_{12} (lauric acid) or more carbon atoms they are solid at room temperature.

All the fatty acids in animal organisms have an even number of carbons. They form four groups: (*a*) saturated fatty acids ($C_nH_{2n}O_2$), *e.g.*, stearic ($C_{18}H_{36}O_2$), palmitic ($C_{16}H_{32}O_2$), and myristic ($C_{14}H_{28}O_2$); (*b*) monoethylenic with only one double bond, *e.g.*, oleic ($C_{18}H_{34}O_2$); (*c*) diethylenic with two double bonds, *e.g.*, linoleic ($C_{18}H_{32}O_2$); (*d*) triethylenic with three double bonds, *e.g.*, linolenic ($C_{18}H_{30}O_2$). The double bonds invest these acids with a greater chemical reactivity, and they are more easily oxidized and combine with a larger quantity of iodine than saturated fatty acids. The iodine number, or iodine value, is the amount of iodine that can be combined by 100 gm. of fat; it indicates the number of double bonds in a fatty acid.

Natural fats contain many different fatty acids, which vary from one species to another. Thus 12 fatty acids have been obtained from butterfat, including oleic, palmitic, myristic, stearic, and others of a shorter carbon chain.

Lipids can be divided into (*a*) simple lipids; (*b*) compound lipids; (*c*) sterols; (*d*) hydrocarbons.

Simple lipids. These are esters of glycerol, or another alcohol, and fatty acids. They can be divided into

1. Fats and oils, usually called neutral fats or glycerides. These are esters of glycerol and fatty acids, corresponding to the following formula: $CH_2OR—CH{\cdot}OR^{I}—CH_2OR^{II}$ (R, R^I, and R^{II} are fatty-acid radicals).
2. Waxes, which are esters of fatty acids and an alcohol other than glycerol; they are of high molecular weight.

Compound lipids. These are esters of fatty acids and alcohols combined with other substances. They can be divided into

1. Phospholipids, made up of fatty acids, glycerol, phosphoric acid, and a nitrogenous base. Among the monoaminomonophospholipids the most important are (*a*) lecithin, which on hydrolysis yields two fatty acids (oleic, and palmitic or stearic), glycerol, phosphoric acid, and choline; (*b*) cephalin, in which the nitrogenous base is aminoethyl alcohol (colamine). Sphyngomyelin is the prototype of diaminomonophospholipids; on hydrolysis it yields fatty acids (lignoceric, stearic, etc.), phosphoric acid, and two nitrogenous bases, choline and sphyngosine.
2. Cerebrosides or glycolipids, which are made up of fatty acids (phrenosinic or lignoceric), galactose or another sugar, and sphyngosine. Phrenosin and kerasin are the two most important in this group.

Sterols. These substances are not true fats, but alcohols with a cyclic nucleus (cyclopentenoperhydrophenanthrene). They are found free or in esters with fatty acids known as "steroids." They are extracted by organic solvents to-

gether with the fats, and in their functions in the organism they are related to the fats.

Hydrocarbons. Many natural fats contain squalene, carotene, and other lipids of considerable physiologic importance, such as vitamins A and D.

The functions of fats. Fats provide food with a high caloric value; 1 gm. of fat yields 9.3 kg.-cal, twice the energy yield of 1 gm. of carbohydrate or protein (4.1 kg.-cal). The usual diet in adults has 50 to 130 gm. of fat; it is difficult to ingest more than 150 gm. daily, because these large amounts are repulsive and difficult to digest. Nevertheless it is possible to increase the fat content of the diet by carefully choosing and preparing the food (butter is well tolerated) and by acquiring the habit; thus Eskimos eat large quantities of fat. From 15 to 35 per cent of the calories in a normal human diet are provided by fat; the optimum amount is from 80 to 100 gm. per day, and it should not be less than 1 gm. per kg. per day.

When considering the fat in the diet it is necessary to examine (*a*) whether there is an indispensable minimum; (*b*) the advantages of food fat; (*c*) the optimum amount a well-balanced diet should contain.

It is difficult to say whether a definite minimum amount of fat is necessary. Men (Hinhede, Pirquet) and rats (Mendel) have been kept in apparent good health on diets with very little fat. A small amount is needed to carry the fat-soluble vitamins and certain indispensable fatty acids.

Rats fed on a diet completely free from fat can be kept in good condition if adequate amounts of fat-soluble vitamins and certain fatty acids are added. Without these indispensable fatty acids the animals in some cases do not survive long, growth is retarded, and cutaneous lesions appear.[1] All these disturbances are cured by adding to the diet small amounts of linolic and arachidonic ($C_{20}H_{32}O_2$) acids; linolenic, decosahexenoic, and other acids improve the animals but do not cure all the disturbances. Palmitic, oleic, and stearic acids, which are the most abundant fatty acids in a common diet, can be eliminated without causing any harm. Although animals and men have been maintained in good health on an almost fat-free diet, this has been

[1] Burr, G. O., and M. M. Burr, *J. Biol. Chem.*, **82**, 345, 1929; **86**, 587, 1930; **97**, 1, 1932; Hansen, A. E., and G. O. Burr, *J. A. M. A.*, **132**, 855, 1946.

done only in carefully controlled experimental conditions. Optimum growth is obtained in rats when 20 to 40 per cent of the diet consists of fat. The optimum amount for man[1] has been given as 30 per cent of the diet in weight and 50 per cent in calories.

Starling has remarked that fat has many advantages in human nutrition. It offers a high caloric value in concentrated form. It satisfies hunger more than other foodstuffs. It is absorbed slowly, thus spreading the provision of energy over several hours, which is very suitable when hard physical labor must be performed in a cold climate (*e.g.*, in northern lumber camps).

Fats are the most important reserves of energy in the organism, and they can be stored with a much smaller proportion of water than carbohydrate or protein. They form approximately 12 per cent of the total body weight; therefore for each kilogram of body weight there is about 120 gm. fat, equivalent to almost 1100 kg.-cal.—over 72,000 kg.-cal. for a man weighing 67 kg. This reserve is the main source of energy in prolonged fasting; 85 per cent of the total calories are obtained from body fat in hibernating animals and in conditions of inanition.

Fats are protein sparers, but they are not as efficient as carbohydrates in this respect. Nevertheless when they are associated with carbohydrates a greater protein-sparing effect is obtained than with carbohydrate alone.

Fats are the vehicle of the natural fat-soluble vitamins, especially of vitamins A, D, and E. In some cases they reinforce the activity of thiamine (vitamin B_1) and other vitamins.

Subcutaneous fat is poorly vascularized, and little blood circulates through it. It therefore forms an insulating layer that prevents the loss of heat from the body into the environment. This fat layer is particularly important for heat regulation in aquatic mammals and in races living in polar regions (Eskimos).

It also has a plastic effect, rounding the contours of the body, which is of esthetic value when not excessive.

There is no satisfactory proof that isolated muscles consume fat directly in the course of muscular contraction. On the other hand the intact organism apparently can utilize fat to provide energy for muscular exercise, but it must first be converted into substances that can be

[1] Deuel, H. J., *J. Am. Dietet. A.*, **26**, 255, 1950.

used directly by the muscles. At the beginning of exercise there is a high RQ as when carbohydrate is being burned;[1] later, in prolonged exercise, the RQ decreases gradually. The previous diet of the subject has a great influence on the RQ of exercise. Thus a subject on a carbohydrate diet has an RQ of 0.90, of 0.80 on a protein diet, and of 0.72 on a fat diet. The efficiency of muscular exercise is only 22 per cent in subjects on a high-fat diet and 24 per cent on a high-carbohydrate diet (Krogh).

The heart muscle seems to consume fat, of which it contains enough to provide the energy it needs to continue beating for 6 to 7 hr. In certain experiments the oxygen consumption and energy output of the heart cannot be accounted for by the carbohydrate and protein consumed. In these cases it is thought that energy is provided by the oxidation of fat.

Methods of study. There are several methods for the study of fat absorption, transportation, and storage and of the chemical processes in which they take part. The following are the methods most used:

1. A fat containing a fatty acid which does not exist in the organism and is easily detected, *e.g.*, erucic acid, found in colza oil, is given by mouth. A fat thus "labeled" can be followed throughout the body.
2. Fats can also be "labeled" by iodine or a dye which is combined with them.
3. More recently, fats have been labeled by introducing into their molecule an isotope that occurs in nature, such as deuterium, or an artificial radioactive isotope, such as C^{14} or P^{32}.
4. Substances that are thought to be intermediary products of metabolism are administered, and their chemical transformations are followed.[2]
5. Valuable information can be obtained by perfusing an isolated organ with blood or a nutrient fluid to which the substance to be tested is added. The amount destroyed, if any, the products of its metabolism, etc., are then determined by chemical analysis of the fluid or blood flowing from the organ.
6. Slices of surviving tissue are placed in flasks with a nutrient fluid. The substance that is being studied is added and the flasks are shaken continuously to renew the fluid in contact with the tissue. After varying intervals the amount of substance destroyed or its metabolic products are determined by microchemical methods. This technique has the advantage of using simplified chemical systems and of allowing many determinations to be made simultaneously. It has given important results, but these cannot always be considered valid for the whole organism, where many more factors come into play.

[1] Part of the CO_2 eliminated during this period is due to the passage of lactic acid into the blood which sets free CO_2 from bicarbonate; part also is due to hyperventilation and the lowering of the CO_2 tension in alveolar air.

[2] For example, it is thought possible that at a certain stage in the oxidation of a substance either oxalic acid or acetic acid is formed. Oxalic acid is given and it is eliminated quantitatively in the urine; then acetic acid is given and it is oxidized completely. It is evident that in this case acetic acid may be an intermediary product, but that oxalic acid cannot be because it is not metabolized.

INTESTINAL ABSORPTION OF FAT

Digestive processes split neutral fats into glycerol and fatty acids; they split phosphatides into fatty acids, glycerol, phosphoric acid, and nitrogenous bases. Fatty acids are in part converted into soaps by combining with alkali, but part remains in the acid state, because of the acidity of the contents of the upper reaches of the intestine. The products of the digestion of fats are absorbed by the intestinal mucosa and are resynthesized into glycerides and phosphatides, passing into the blood and lymph as such. Fats in maternal plasma pass through the placenta into the fetus.

There is from 4 to 12 per cent fat in the feces, but all this does not come from ingested food. Experiments in fasting animals and in others fed on a fat-free diet have shown that the intestinal mucosa excretes a small amount of fat—approximately 220 mg. per kg. of body weight per day in the dog.[1] Part of the fat found in feces is in bacteria and in cells shed by the intestinal mucosa.

Almost all the fat ingested (more than 95 per cent in man) is digested and absorbed. Fats with a high melting point are less readily absorbed.

Hydrolysis of fats was considered until recently a necessary preliminary to their absorption. Fatty acids set free by hydrolysis of all fat were supposed to be absorbed in the form of soluble soaps (Pflüger). Two circumstances cast doubts on the accuracy of this interpretation: (*a*) the contents of the upper part of the small

[1] SPERRY, W. M., and R. W. ANGEVINE, *J. Biol. Chem.*, **96**, 769, 1932.

intestine are too acid (pH 6.5) for the formation of soaps, and (*b*) the small amount of base available[1] is not sufficient for all the fatty acid which would be released by hydrolysis of all the fat in the food.

Bile plays an important part in the absorption of fats. Bile acids form complex systems with oleic, palmitic, and stearic acids. These systems are soluble in water, are highly diffusible, and pass easily through organic membranes. The effect of bile on fat absorption is due to this property of bile acids, known as hydrotropism (Neuberg). According to Verzár, fats are completely hydrolyzed; the fatty acids thus released combine with the bile acids and penetrate into the intestinal epithelium, where the bile acids are set free and returned to the lumen of the intestine. The fatty acids are converted into phosphatides and then into neutral fats. This phosphorylation is catalyzed by an enzyme which is found in high concentration in the intestinal mucosa.

Frazer[2] maintains that part of the fats are absorbed without previous hydrolysis. Lipolysis is slowed down *in vitro* when 30 per cent of the fatty acid has been released. Partial hydrolysis of fats produces monoglycerides, diglycerides, and fatty acids which together with the bile acids emulsify nonhydrolyzed glycerides. The only efficient system capable of emulsifying fats in the upper part of the intestine, with the formation of droplets of 0.5 μ average diameter, is constituted by bile acids, fatty acids, and monoglycerides. This system permits the absorption of triglyceride, without the need of complete hydrolysis into fatty acids and glycerol. Absorption depends on the diameter of the droplets; thus paraffin is not finely emulsified in the intestine and is not absorbed, but if it is administered emulsified in droplets of 0.5 μ, negatively charged, it seems that it can be absorbed.

Glycerides and long-chain fatty acids apparently penetrate into the fine channels in the outer border of the cells lining the intestine. Monoglycerides and diglycerides are converted into phospholipids or triglycerides; the latter passing into the lymph in the form of droplets. Fatty acids with a short chain and some of the phospholipids behave as water-soluble substances and pass directly into the blood of the portal system and are carried to the liver. There is, however, no final agreement as to these processes.

[1] SCHMIDT, N. K., *Acta physiol. Scandinav.*, **12**, Suppl. 37, 1951.

[2] FRAZER, A. C., *Physiol. Rev.*, **26**, 103, 1946; *Bull. Soc. chim. biol.*, **33**, 961, 1951.

Detergents, such as polyoxyethilene sorbitan mono-oleate (PSM, Tween 80), which emulsify fats have been used in the treatment of diseases where fat absorption is deficient.

The simultaneous presence of the pancreatic juice and the bile is of great importance for the absorption of fats. Pancreatic juice hydrolyzes fats; bile aids this action and facilitates absorption. In the rabbit the bile duct opens into the intestine about 30 cm. above the opening of the pancreatic duct; absorption of fat and the filling of the lacteals begins only at the level where the pancreatic juice is poured into the gut (Bernard).

If the pancreatic juice is absent, 50 to 60 per cent of ingested fat is found in the feces. If the bile only is absent, 30 to 80 per cent is found in the feces, but in this case it is hydrolyzed. If both pancreatic juice and bile are missing, 80 to 90 per cent of the ingested fat is lost in the feces. Steatorrhea (fatty feces) is also observed when there is an excessively rapid passage through the digestive tract or when the intestinal mucosa is damaged, as occurs in certain chronic diarrheas and in celiac disease.

Sinclair[1] maintains that fats are phosphorylated before being absorbed; they are first converted into phospholipids in the intestinal mucosa and then secreted into the blood as neutral fats (glycerides). Phosphorylation of fats has been demonstrated in many experiments: (*a*) after administration of fatty acids easily identified, such as elaidic acid, these are found in phospholipids; (*b*) after ingestion of fatty acids "labeled" by incorporating iodine or deuterium into their molecule, these are also found in phospholipids; (*c*) after ingestion of radioactive phosphorus (which has been used in similar studies) it is found in phospholipids, first in the intestine and liver, later in tissues and fat stores.[2] Glycerophosphates and choline (Honorato) increase intestinal fat absorption.[3]

[1] SINCLAIR, R. G., and C. SMITH, *J. Biol. Chem.*, **82**, 117, 1929; **111**, 260 and 275, 1935; **121**, 361, 1937; *Biol. Symposia*, **5**, 82, 1941.

[2] PERLMAN, I., S. RUBEN, and L. CHAIKOFF, *J. Biol. Chem.*, **122**, 169, 1937.

[3] VERZÁR, F., and L. LASZT, *Biochem. Ztschr.*, **270**, 24 and 35, 1934; **278**, 396, 1935; **288**, 351, 1936.

According to Verzár, fats and some of the sugars (glucose and galactose) must be phosphorylated to be rapidly absorbed. If phosphorylation is inhibited by monoiodoacetic acid or phlorhizin, absorption of these substances is retarded or inhibited even when glycerophosphates are given. Several arguments have been opposed to this theory, *e.g.*, drugs that inhibit fat absorption also damage the intestinal mucosa and retard the absorption of substances that are not phosphorylated. Verzár thought that cortico-adrenal hormones were necessary for phosphorylation, and that deficiencies in absorption observed in adrenalectomized or hypophysectomized animals were due to their absence. Nevertheless these hormones are not indispensable for absorption, as it is enough to control adrenal insufficiency by the administration of sodium chloride to restore a normal rate of absorption. Disturbances in water and salt metabolism seem to be the main cause of abnormalities in absorption in adrenal insufficiency.

Although phospholipids are formed in the intestinal mucosa, many experiments have proved that fats are absorbed mainly as neutral fats, not as phosphatides.[1] These perhaps act as intermediary substances, but not as end products in the resynthesis of fat (Schmidt-Nielsen, Bloom).

In the course of absorption of fats, fatty droplets appear within and between the cells of the intestinal mucosa; these droplets are not there in the fasting animal. Only part of the intracellular content of lipids is revealed by histologic stains, though sudan reveals more than osmic acid. The fat droplets accumulate gradually within the cell to a maximum in the course of 1 hr. or more. Later they diminish, disappearing in about 6 hr.

While fats are being absorbed the intestinal lymphatics become visible because they are filled with a milky fluid; for this reason, they are called lacteals. The milky aspect of the lymph is due to the numerous fine fatty globules that are being secreted into it from the intestine.

Munk found 60 per cent of ingested fat in the lymph collected from a patient with a fistula of the thoracic duct. The results of this observation have been confirmed in many experiments on animals. It is usually said that 60 to 70 per cent of ingested fat is absorbed by the lymphatics and 30 to 40 per cent by the blood capillaries. No accuracy can be attributed to these figures, because part of the fat in the lymph is not absorbed but endogenous fat; moreover, part of the absorbed fat in intestinal lymph can go into the veins without passing through the thoracic duct.

There are no free fatty acids in lymph—only glycerides of fatty acids, arising partly in the body and partly in ingested fat; these are always found as glycerides even when esters of other alcohols are ingested. When palmitic acid labeled with C^{14} is given to unanesthetized rats, 70 to 92 per cent of the amount absorbed is found in thoracic duct lymph, and 96 per cent in the intestinal lymph.[1]

Fatty acids in the blood plasma and erythrocytes increase during the absorption of fat. Cholesterol and cholesterol esters have a tendency to increase, especially in the erythrocytes. Phosphatides also show some increase; they are in part formed from absorbed fatty acids. The blood plasma takes on a milky aspect, due to the numerous very fine fatty globules suspended in it. These particles, known as chylomicrons or lipomicrons or hemoconia, are fine droplets of glycerides surrounded by a protein layer. Their size is 1 μ or less. They are well visualized on a dark field, and can be counted. Lipemia does not always increase during absorption; when it does not, probably fats are retained by the tissues or rapidly stored as they are absorbed.

Fat is transported from the intestine to the tissues in the form of phospholipids, cholesterol esters, and glycerides. Part of the glycerides are transported in lipoproteins.

Lipemia. Chemical methods for blood-fat analysis have been improved sufficiently to give a fairly accurate picture of the blood fat and its changes. The concentration of blood fat in the fasting subject varies considerably in different species[2] and individuals. Even the same individual has widely different figures from one day to another. Table 44 gives the average concentration of the blood fats observed by accurate workers.

Phosphatides and neutral fats are in approximately the same concentration. The greater

part of blood cholesterol is combined in esters; only a small part circulates as free cholesterol. Fats are combined with the plasma protein and form lipoprotein compounds which, in spite of containing 35 to 75 per cent fat, are soluble in water, giving perfectly transparent solutions (Macheboeuf, Cohn).

liver; (*d*) oxidized; (*e*) excreted in milk, in the skin secretion, and in small quantities in the feces. Two kinds of fat are differentiated:

1. Fat that forms part of the tissues. This fat is constant and is not changed by fasting. It has a high iodine number and a large proportion of phospholipids (Terroine's "*élément constant*").[1]
2. Storage fat, which varies considerably with the diet and is diminished by fasting (Terroine's "*élément variable*"). It is mainly made up of glycerides.

There is hyperlipemia (a rise in blood fat) when there is an increase in the fat being transported from one place to another, as in the following circumstances: (*a*) during the post-absorptive period; (*b*) in prolonged fasting or exercise; (*c*) in subjects under the effects of anesthetics or alcohol; (*d*) during pregnancy and lactation, in subjects of both sexes treated with estrogens, and in females treated with gonadotrophins; (*e*) during the laying season in hens and immediately before and during laying in pigeons; (*f*) after repeated injections of anterior hypophyseal extracts (marked hyperlipemia); (*g*) in severe experimental and human diabetes; (*h*) in nephrosis and anemia. Hypercholesterolemia is observed in nearly all these circumstances, being especially marked in pregnancy, severe diabetes, and thyroid insufficiency. Phospholipids increase during pregnancy and diminish after insulin injections.

THE ORIGIN AND FATE OF FAT IN THE ORGANISM

Fats in the organism have their origin in the fat absorbed from the food and in the conversion of carbohydrate and protein into fats.

Absorbed fats are (*a*) deposited as storage fat; (*b*) incorporated into the constituent fats of the tissues; (*c*) converted and deposited in the

Tissue cells sometimes contain not only constituent fats but also variable amounts of storage fats.

STORAGE FATS

Composition. Storage fats vary in different species; thus sheep fat is firmer than beef fat. These differences are due to the dietary and metabolic characteristics of the various species. Fatty acids in the stored fats come mainly from the food fats, but they are modified to a certain extent, their composition approximating that of the animal's fat.

Stored fat does not remain inert in the tissues, as might be supposed from its name. On the contrary, it is being continuously removed for utilization and replaced by new amounts, and there is unceasing metabolic activity in the fat stores. Chemical analysis shows that there is a balance between fat entering and leaving the

[1] TERROINE, E. F., Fat Metabolism, *Ann. Rev. Biochem.*, **5**, 227, 1936.

stores. The chemical mechanisms of fat storage and mobilization are not yet well known.

About half the storage fat in the body is found in the subcutaneous adipose tissue; 10 to 15 per cent in the renal space; 10 to 15 per cent in the mesentery, in the omentum, and under the peritoneum; and 5 per cent between the muscles. The external aspect, microscopic structure, and chemical composition of these fats vary from one part of the body to the other. The melting point of human fat varies from 0.5 to 41°C. in the different stores. It is usually liquid at 37°C. owing to the large proportion of oleic acid it contains. The average composition of human storage fat is given in Table 45.

Table 45. Composition of Human Subcutaneous Fat

Acids	*Cattaneo and Calandra**		*Cramer and Brown†*
	% of fat	*% of total fatty acids*	*% of total fatty acids*
Myristic (tetradecanoic)	1.4	1.5	2.7
Palmitic (hexadecanoic)	19.8	20.8	24.0
Stearic (octadecanoic)	2.0	2.2	8.4
Arachidic (eicosanic)	0.1	0.1	
Myristoleic (tetradecenoic)	0.4	0.4	0.2
Palmitoleic (hexadecenoic)	3.0	3.2	5.0
Oleic (9-octodecenoic)	36.8	38.7	46.9
Linoleic (9,12-octodecadienoic)	23.6	24.8	10.2
Gadoleic (9-eicosenoic)	2.6	2.8	1.5
Eicosadienoic	3.2	3.3	
Arachidonic (eicosatetraenic)	0.4	0.4	1.0
Erucic (docosenoic)	1.7	1.8	
Iodine number	91.7		68.9
Saponification number	192.4		196.5

Note: There is a small amount of squalene (Cattaneo and Calandra) and approximately 1 per cent cholesterol and 0.5 per cent lecithin; 0.1 per cent lauric acid is also reported (Cramer and Brown).

* Calandra, E., and P. Cattaneo, *Rev. Soc. argent. de biol.*, **24**, 275, 1948.

† Cramer, D. L., and J. B. Brown, *J. Biol. Chem.*, **151**, 427, 1943.

In some animals living in cold climates, the iodine number and melting point of fats increase with their depth from the body surface.[1] This is not observed in animal species not commonly exposed to a cold climate.[1]

[1] Henriquez, V., and C. Hansen, *Skandinav. Arch. f. Physiol.*, **11**, 151, 1901.

Fat arising from food-fat. The composition of storage fat can be markedly modified by giving an excess of certain fats in the food. Thus, the subcutaneous fat of a dog fed on linseed oil remains liquid at 0°C.; it becomes firmer and the melting point rises to 50°C. when the dog is fed on mutton fat, which has a large proportion of stearic acid.[2] The administration of colza oil, which has erucic acid, is followed by the appearance of this acid in the fat stores, although it is not a normal constituent of body-fat.[3] Animals have been fed fatty acids "labeled" with iodine, dyes, or deuterium, and these have later been found in their storage fats. Table 46 summarizes some of Anderson and Mendel's experiments on the influence of ingested fat on the composition of storage fat.

In fasting animals the first fats to be mobilized are liquid fats and fatty acids with double bonds (Anderson and Mendel). Hog breeders have observed that submitting the animals to a short fast before slaughtering them renders their fat more firm, especially if they have been fed a diet rich in oil.

Schoenheimer has fed animals with several fatty acids containing C^{14} in their molecule, so as to identify them in the organism. The greater part of those with more than 10 carbon atoms is stored and later utilized. Fatty acids with a shorter chain are either oxidized without delay or else converted into higher fatty acids.[4]

Table 46. Iodine Number of Fat in Diet and Body-fat in Rats Fed a Diet with 60 Per Cent of Total Calories in Fat

Food	*Iodine number*	
	Food-fat	*Body-fat*
Soya oil	132	123
Corn oil	124	114
Linseed oil	108	107
Bacon fat	63	72
Butterfat	36	54

[2] Lebedeff, A., *Pflüger's Arch. f. d. ges. Physiol.*, **31**, 11, 1883.

[3] Munk, L., *Arch. f. Anat. u. Physiol.*, **95**, 407, 1884.

[4] Powell, M., *J. Biol. Chem.*, **89**, 43, 1930.

One fatty acid is readily converted into another. Thus stearic acid (C_{18}) is desaturated into oleic acid, or loses two carbon atoms, giving palmitic acid (C_{16}). The chain of palmitic acid can be lengthened into stearic acid or broken down into acids with a shorter chain. Desaturation can take place in the animal organism, but only as far as one double bond; fatty acids with two double bonds come exclusively from food-fat.

Fatty acids are synthesized by successive condensations of two carbon atoms. If acetic acid containing deuterium is given to an animal, the deuterium will be found in the higher fatty acids of its body.[1]

The fat in milk is also modified by the fats in the food, a fact demonstrated by experiments made in lactating cows and bitches. Thus the iodine number of the milk fat rises from 30 to 70 in a cow fed on linseed oil. The taste of milk is due in great part to the fat in the food.

Conversion of carbohydrate into fat. The old popular belief that carbohydrate food is fattening was demonstrated scientifically first by Liebig (1852) and Lawes and Gilbert (1859) and has since then been repeatedly confirmed. A young suckling pig was slaughtered and its body-fat and protein analyzed; another animal from the same litter was fed on a diet with abundant carbohydrate and after a time was slaughtered and analyzed. The increase in body-fat was more than could be accounted for by the protein and fat in the food; therefore it must have been produced by the conversion of carbohydrate (Table 47).

Fat formed from carbohydrate has a high melting point and a low iodine number, *i.e.*, it is made up of saturated fatty acids. Schoenheimer and his associates have shown that palmitic and stearic acid are formed at a much higher rate than nonsaturated fatty acids. According to McHenry *et al.*,[2] certain vitamins in the B complex are necessary for the conversion of carbohydrate into fat. Thiamine is especially important; riboflavin, pyridoxine, and nicotinic acid play a similar but less prominent part in this process.

Experiments in which glucose labeled with deuterium has been given have shown that only 3 per cent of the glucose given is stored as glycogen, while 10 times this amount is converted into fatty acids (Stetten *et al.;* see Chap. 41). The stages in the chemical process of this conversion are not yet known, although possible mechanisms have been discussed. Its RQ is approximately 1.4. There is deficient formation of fat from glucose (Stetten) or acetate (Brady and Gurin) in diabetes. Insulin accelerates the normal conversion of food carbohydrates into fat; also transport of fat from the liver to the tissues (lipokinetic action).

Table 47. Conversion of Carbohydrate into Fat in Pigs

	Pounds
Total fat increase	71.2
Fat in food	12.4
Fat synthesized	58.8
Carbon in synthesized fat	45.3
Protein in food	64
Body-protein increase	6.5
Protein available for fat synthesis	57.5
Carbon in 57.5 lb. protein	27.4

Carbon in synthesized fat obtained from carbohydrate
$45.3 - 27.4 = 17.9$

Source: Lawes and Gilbert, 1859 and 1877.

Conversion of protein into fat. Sixty per cent of the protein intake can be converted into fat; it is therefore logical to suppose that protein can be a source of storage fat. Conversion of protein into fat has been demonstrated by feeding animals on an exclusively protein diet.[1] Firm fat is formed such as arises from carbohydrate. The process is accelerated by pyridoxine, but not by thiamine. Nevertheless not much fat can have its origin in protein, because deamination of amino acids gives rise to fatty acids with a short chain, which are easily oxidized.

Conversion of fat into carbohydrate. Probably fat can be converted into carbohydrate, since the opposite process (conversion of carbohydrate into fat) takes place in the organism, and glycerol can undoubtedly be converted into carbohydrate. Glycogen and blood sugar do not increase after feeding animals with fatty acids, with the exception of propionic acid; neither does fat ingestion increase the sugar in blood or urine of diabetic animals. The RQ corresponding to the conversion of fat into carbohydrate is 0.3. Such a low figure has been registered over a long period in hibernating

animals only. Over short periods it might be due to temporary retention of CO_2 and not to carbohydrate formation from fat. The passage of C^{14} from fatty acids into glycogen has been observed, and part of C^{14} in palmitic acid given to diabetic dogs has been found in glucose eliminated in the urine.[1] This, however, may be explained by the fact that fats as well as carbohydrates are metabolized in the tricarboxylic cycle (see Chap. 34).

The Role of the Liver in Fat Metabolism

Many observations made in normal and abnormal conditions show that the liver plays an important part in fat metabolism.

Fat content of the liver. Usually the liver contains 3 to 5 per cent fat; one-half to two-thirds of this is made up of phospholipids; the rest is glycerides. According to the circumstances the liver stores variable amounts of fat, phospholipids, or cholesterol. In certain pathologic cases up to 50 per cent of the liver weight can be fat; no other organ ever contains such a large proportion.

Phospholipids and glycerides in the liver have a greater proportion of unsaturated fatty acids than those found in other tissues. This has been attributed to selective storage of these acids or to the liver having the capacity of introducing double bonds into fatty acids, thus facilitating oxidation.[2] The formation of unsaturated fatty acids has been observed in slices of surviving hepatic tissue.[3] In animals fed with saturated fatty acids labeled by deuterium, unsaturated fatty acids containing deuterium are found.[4]

Phospholipids are formed by the liver at a higher rate than in any other organ, except the intestinal mucosa during absorption, and they are rapidly secreted into the blood; thus the liver is the main source of blood phospholipids. Acetate is converted in the liver into neutral fats and phospholipids; fat is usually formed at a faster rate, so possibly phospholipids are not necessary intermediate substances.[5]

Ketone bodies are formed in the liver in the course of oxidation of fatty acids (see "Ketogenesis and ketolysis," page 443).

Liver fat and fatty liver. The fat content of the liver depends on the balance between fat formed or stored in the liver and fat secreted from the liver. The fat in the liver has its origin in (*a*) fats in the food (*B* in the diagram); (*b*) other fat stores (*E*); (*c*) synthesis of fat in the liver (*A*). Fat that disappears from the liver is either broken down and oxidized in the hepatic cells (*C*) or secreted into the blood and transported to other fat stores (*D*).

B
Fat in diet
A C
In certain cases the liver is infiltrated by fat. In the so-called fatty degeneration of the liver, intracellular deposition of fat can be observed histologically. Eventually this accumulation of fat disturbs the functions of hepatic cells. A larger amount of fat is revealed by chemical analysis than by observation under the microscope; the difference between the two is called "masked fat."

Among the principal causes of fatty liver the following can be mentioned:

1. Dietary factors: excess of fat, cholesterol, cystine, thiamine, or biotin; prolonged fasting or insufficiency of protein, choline, methionine, or other lipotropic factors.
2. Extensive partial hepatectomy. There is a marked rise in the fat content of the remaining hepatic tissue, which commences a few hours after the operation and lasts several days.
3. Endocrine factors: (*a*) in pancreatic and severe forms of other experimental diabetes, and human diabetes; (*b*) following injection of anterior hypophyseal extract, somatotrophin or adrenocorticotrophin; (*c*) in pregnancy (the glycerides, phospholipids, and cholesterol increase); (*d*) at the beginning of sexual maturation.
4. Toxic factors: phosphorus, chloroform, alcohol, phlorhizin, etc.

5. Infectious or degenerative processes; *e.g.*, in yellow fever.
6. Environment: very high or very low temperatures; hypoxia.

Fatty infiltration creates favorable conditions for degenerative processes and eventually can end in cirrhosis of the liver. On the contrary, carbohydrate protects the liver, but only if there is an adequate amount of protein in the diet. It is usually admitted that fat and carbohydrate accumulation in the liver cells are mutually antagonistic, but there are many exceptions to this rule.

Diets with excess fat and deficient in protein, cystine, or methionine may cause necrosis of the liver, *i.e.*, the death of the hepatic cells.

Lipotropic and antilipotropic factors. Lipotropic factors are substances that prevent the accumulation of excess of fat in the liver, and diminish the fat content of the liver when it is excessive. The principal lipotropic substances are (*a*) choline and substances chemically related to choline, *e.g.*, betaine; (*b*) methionine and proteins containing methionine; (*c*) inositol; (*d*) certain substances extracted from the pancreas.

Antilipotropic factors are substances which oppose the lipotropic effect of choline and other lipotropic factors and which in high doses create conditions favorable to fatty infiltration of the liver. Cystine, thiamine, cholesterol, biotin, etc., are antilipotropic substances.[1]

The lipotropic effect of choline was discovered as follows: Pancreatectomized dogs maintained free from diabetes by insulin treatment could nevertheless not be kept alive for a very long time. A fatty liver was observed in these animals, and the fatty infiltration could be prevented or cured by adding pancreas to the diet. Then it was found that lecithin had this activity,[2] and when the products of its hydrolysis were tested, choline was found to be the active substance (Best *et al.*, 1932 to 1934).

$$OHCH_2{\cdot}CH_2{\cdot}N \begin{cases} OH \\ (CH_3)_3 \end{cases}$$
Choline

[1] McHenry, E. W., and G. Gavin, *J. Biol. Chem.*, **125**, 627, 1938.

[2] Hershey, G. M., and S. Soskin, *Am. J. Physiol.*, **98**, 74, 1931.

Other substances have been shown to have the same effect, among them homocholine (which is even more active than choline), betaine, methionine and proteins containing methionine, etc.[1] All these substances have this activity because they possess methyl groups which are used in the formation of choline. A very small amount of choline (5 mg. in the rat) is sufficient to prevent fatty infiltration of the liver produced by anterior hypophyseal extract or any other cause.

There are lipotropic factors in pancreatic tissues free from choline. An active principle known as lipocaic[2] has been discovered,[3] but it has not yet been obtained in pure form. According to Chaikoff, there is an anti-fatty liver factor (AFL) in pancreatic tissue and pancreatic juice. This factor has proteolytic activity and permits utilization of methionine in proteins.[4]

Dragstedt *et al.* maintain that pancreatectomized dogs suffer from an insufficiency of lipocaic, which can be compensated by the ingestion of pancreas or of lipocaic. This insufficiency has the following results: glycosuria diminishes, in spite of decreased doses of insulin; hypoglycemic crises frequently occur; hepatic functions are depressed; there are low blood fat, general weakness, anorexia, and emaciation; eventually the animal dies. Administration of lipocaic is followed by a decrease in liver fat and an increase in glycosuria and the insulin requirement, while the condition of the animal improves.

There are differences in the chemical mechanisms by which the lipotropic factors produce their effect on the fatty liver, arising from different causes.

Choline and inositol accelerate the formation of phospholipids from liver fat; these phospholipids are then secreted from the liver. Choline is incorporated into the phospholipid molecule. This has been demonstrated by administering choline labeled with arsenic, heavy nitrogen, or radioactive phosphorus, which is later found in lecithin formed in the liver. When there is not enough choline, fat accumulates in the liver because it cannot be converted into phospholipids and thus mobi-

lized. Methionine and proteins containing it produce choline; to this is due their lipotropic activity.

The fatty liver produced by anterior hypophyseal extract is due to the accumulation in the liver of fat coming from other fat stores. The fatty liver caused by insufficient choline is due to the non-mobilization of liver fat. The fatty liver provoked by cystine or thiamine is apparently due to excessive synthesis of fatty acids (Stetten and Salcedo).

Diets deficient in protein can provoke fatty degeneration and eventually cirrhosis of the liver, causing high mortality, especially in children. This nutritional deficiency (kwashiorkor and allied diseases) has been reported in communities in Africa, the West Indies, Chile, etc.

The Role of the Lung in Fat Metabolism

According to Roger and Binet,[1] fat absorbed by the lacteals is carried by the blood to the lungs, where it is fixed (lipopexia) and then disintegrated (lipodieresis). Other workers have found this process to be of secondary importance.[2]

The Role of the Endocrine Glands in Fat Metabolism

Some of the endocrine glands play an important part in fat metabolism, which will be considered in the chapters on the glands in question.

The Role of the Nervous System in Fat Metabolism

Extreme obesity has been observed in rats,[3] dogs,[4] and monkeys[5] after certain experimental lesions were produced in the hypothalamus. This effect is apparently due to hyperphagia; the animals have a huge appetite and eat great quantities of food very rapidly.[6] (See page 1081.)

Transmethylation[7]

It has been proved that in the tissues of several animals, including man, methyl groups can be transferred from one substance to another. A normal diet contains substances that can supply methyl groups for this process. If they are absent, growth ceases, the liver becomes infiltrated by fat, there is hemorrhage into the renal tubes, and eventually death occurs. If a methyl donor such as choline, betaine, or methionine is added to the diet, these disturbances are prevented or cured.

Methyl groups play a part in the metabolism of nitrogen, sulfur, protein, carbohydrate, and fat.[1] Methionine is one of the amino acids essential for the maintenance of a normal nitrogen balance, growth, and even life. Methionine can be formed by transference to homocysteine of a methyl group from choline or betaine. The methyl groups of methionine are used in the formation of choline, which exerts lipotropic activity in the liver. The methyl groups of methionine are also used for methylation of creatine, creatinine, adrenaline, etc. These processes of transmethylation have been demonstrated by labeling the methyl with deuterium or C^{14}. Vitamin B_{12} accelerates methyl biosynthesis.

The Functions of Phospholipids

The liver, heart, kidney, spleen, lung, and other viscera have 2 to 4 per cent ether-soluble extract, of which one-half to two-thirds is phosphatides, the remainder being glycerides and cholesterol. The phospholipid content of a tissue is directly proportional to its functional activity (Bloor). It appears that phospholipids are the main form in which fat is transported in the organism, owing to their solubility in water and high fatty-acid content (70 per cent). They are also highly reactive and easily oxidized substances because they have more unsaturated fatty acids than the glycerides. The liver and the intestinal mucosa are the sites of greatest activity in the synthesis of phospholipids.

The formation of phospholipids is of importance in the absorption of fat, according to some observers, because part of the fat in food is phosphorylated in the intestinal mucosa. Choline and inositol, as has been noted above, prevent the accumulation of fat in the liver because they speed up production and oxidation of phospholipids in the liver cell.[2] Probably most

of the fat entering and leaving the cells is in the form of phospholipids.

It has been remarked that the fat and phospholipid content of certain organs (brain, kidney, lung, spleen, and heart) varies little under the influence of fasting or changes in diet. This has been called the constant or specific constituent fat of each tissue.[1] The term is not quite appropriate because this fat is not static and unchangeable; on the contrary, the constancy of the fat content is due to a dynamic equilibrium between the fat entering and formed in the tissues on one hand, and that leaving and destroyed on the other. The administration of phospholipids with radioactive phosphorus has shown that there is a continuous intake and output of these substances in the tissues. The quickest exchanges are observed in the intestinal mucosa, those in the liver come next, in the heart and muscle they are less rapid, and in the brain they are even slower. The concentration of phospholipids is fairly constant for each organ, but the fatty acids that form part of them vary according to the nature of the fatty acids in the diet.

Apart from these constituent fats (mainly phospholipids), in special circumstances certain tissues, such as muscle, and particularly the liver, can store variable, sometimes considerable, amounts of fat.

Phospholipids are of fundamental importance in the functioning of the cells. They are a permanent constituent of the cell membrane and protoplasm. Their loss causes serious anatomic and physiologic disturbances. The ratio of phospholipids to cholesterol is maintained constant in the cells, and this appears to be important for the permeability of the membrane, hydration of the protoplasm, etc. In some cases phospholipids and cholesterol have opposite effects, and an equilibrium is kept between them in normal conditions. For example, cholesterol neutralizes the intense hemolytic activity of lysocythin and lysocephalin produced by the disintegration of lecithin and cephalin caused by certain phosphatidases, such as that of cobra venom.

Table 48. Oxidation Products of Fatty Acids

Acid ingested	*Oxidation product*	*Acid excreted*
Benzoic ($C_6H_5 \cdot COOH$)	Not oxidized	Hippuric
Phenylacetic ($C_6H_5 \cdot CH_2 \cdot COOH$)	Not oxidized	Phenaceturic
Phenylpropionic ($C_6H_5 \cdot CH_2 \cdot CH_2 \cdot COOH$)	$C_6H_5 \cdot COOH$	Hippuric
Phenylbutyric ($C_6H_5 \cdot CH_2 \cdot CH_2 \cdot CH_2 \cdot COOH$)	$C_6H_5 \cdot CH_2COOH$	Phenaceturic
Phenylvaleric ($C_6H_5 \cdot CH_2 \cdot CH_2 \cdot CH_2 \cdot CH_2 \cdot COOH$)	$C_6H_5 \cdot COOH$	Hippuric

OXIDATION OF FAT AND KETOGENESIS

The final products of fat metabolism are CO_2 and water. Glycerol and fatty acids (the two components of neutral fats) undergo widely different processes. Glycerol follows the same path as carbohydrate, probably after phosphorylation. It can be utilized as a source of glycogen in normal animals, and it increases glycosuria in diabetic animals.

The fatty acids found in greatest amounts in the organism are palmitic acid, which has 16 carbon atoms in its chain ($CH_3 \cdot (CH_2)_{14} \cdot COOH$); stearic acid, with an 18-C chain ($CH_3 \cdot (CH_2)_{16} \cdot COOH$); and oleic acid, with an 18-C chain ($CH_3 \cdot (CH_2)_7 \cdot CH = CH \cdot (CH_2)_7 \cdot COOH$). Oxidation of these acids has been studied mainly by three methods: (*a*) the administration of acids combined with a benzene ring (Knoop's experiments); (*b*) measuring the formation of ketone bodies in the organism or in slices of surviving tissues; (*c*) the administration of fatty acids labeled by an isotope (deuterium or C^{14}).

These methods have shown that fatty acids are oxidized at the β-C (the third C counting from the carboxyl group), and a substance with two carbon atoms is separated. By a series of successive oxidations, the fatty-acid chain thus loses its carbon atoms two by two. Two molecules of the two-carbon substances formed can combine and give ketone bodies that have four

[1] MAYER, A., and G. SCHAEFFER, *J. de physiol. et de path. gén.*, **15**, 510, 1913; **16**, 1, 1914; TERROINE, E. F., "Physiologie des substances grasses," Paris, 1919; *Ann. Rev. Biochem.*, **5**, 227, 1936.

carbon atoms, or they can be oxidized following the tricarboxylic cycle. Ketone bodies are also oxidized by the tissues, and in normal animals only a small amount passes into the urine.

Knoop's experiments. The now classic work of Knoop[1] showed that fatty acids undergo β-oxidation and that the chain loses its carbon atoms by pairs. He gave animals phenyl derivatives with a fatty-acid side chain (Table 48) and observed that, when the fatty-acid chain had an even number of carbon atoms, disintegration of the derivative ended in phenylacetic acid. On the other hand, phenyl derivatives with a side chain of an odd number of carbon atoms ended in benzoic acid. Phenylacetic acid and benzoic acid are eliminated in the urine combined with glycine in the form of phenaceturic and hippuric acids, respectively. The amine group of glycine combines with the carboxyl of phenylacetic or benzoic acid, as in the peptide linkage of proteins. Results obtained by the administration of some phenyl derivatives are summarized in Table 48.

Knoop concluded that the fatty-acid chain was always oxidized in the β-carbon; the chain, breaking at the bond between the α- and β-carbons, is shortened by two carbon atoms at a time. Thus stearic acid, which has 18 carbon atoms, gives palmitic acid with 16 C, which in turn gives myristic acid (14 C), then lauric acid (12 C) is formed, and so on down to butyric acid (4 C), which would be oxidized into ketone bodies, the latter also undergoing final oxidation into CO_2 and water. This theory gives a simple explanation of how ketone bodies are formed, as can be seen in the following diagram:

$$\overset{\omega}{CH_3}\cdot CH_2\cdot CH_2\cdot \overset{\beta}{CH_2}\cdot \overset{\alpha}{CH_2}\cdot COOH \quad \text{Caproic acid}$$
$$\downarrow \beta \text{ oxidation}$$
$$CH_3\cdot CH_2\cdot CH_2\cdot CO\cdot CH_2\cdot COOH$$
$$\downarrow \beta \text{ oxidation and disintegration}$$
$$CH_3\cdot CH_2\cdot CH_2\cdot COOH + CH_3\cdot COOH \quad \text{Butyric + acetic acids}$$
$$\downarrow \beta \text{ oxidation}$$
$$CH_3\ CO\cdot CH_2\cdot COOH \quad \text{Acetoacetic acid}$$

Later work has shown that β-oxidation does take place, but that the final stages are not those postulated by Knoop.

The formation of ketone bodies. Oxidation of fat and of some amino acids in the organism gives rise to the so-called "ketone bodies," *i.e.*, acetoacetic acid, β-hydroxybutyric acid, and acetone.

This denomination is not strictly accurate, because although acetoacetic acid and acetone are ketones, β-hydroxybutyric acid does not have a ketone group:

$CH_3\cdot CO\cdot CH_2\cdot COOH$	Acetoacetic acid
$CH_3\cdot CH\cdot OH\cdot CH_2\cdot COOH$	β-Hydroxybutyric acid
$CH_3\cdot CO\cdot CH_3$	Acetone

The term is nevertheless in common usage because variations of β-hydroxybutyric acid in the organism are parallel to those of acetone and acetoacetic acid.

Acetoacetic acid is the first substance formed. It is readily converted by reduction into β-hydroxybutyric acid. This process is activated by a specific enzyme, β-hydroxybutyric dehydrogenase, and a coenzyme, diphosphopyridinenucleotide (see Chap. 34).

Acetone is formed by decarboxylation of acetoacetic acid, a process that takes place without enzymes. Acetone excreted in the urine and the breath has a typical smell.

Embden and Marx[1] showed that a liver perfused with fatty acids containing an even number of carbon atoms produced a large amount of acetoacetic acid. The same result was obtained when slices of surviving liver were used.[2] This method is more precise than the perfusion method, and it has revealed that fatty acids with an odd number of carbon atoms also give rise to acetoacetic acid, but in much smaller quantities than fatty acids with an even number of carbon atoms.

Experiments with slices of surviving tissue also show that fatty acids with an even number of carbon atoms give rise to a larger amount of acetoacetic acid than might be expected if from

[1] KNOOP, F., *Beitr. z. chem. Physiol. u. Path.*, **6**, 150, 1904.

[1] EMBDEN, G., and A. MARX, *Beitr. z. chem. Physiol. u. Path.*, **11**, 318, 1908.

[2] QUASTEL, J. H., and A. H. M. WHEATLEY, *Biochem. J.*, **27**, 1753, 1933.

each molecule of fatty acid one molecule of acetoacetic acid were formed. It is therefore necessary to admit that the two-carbon-atom fragments broken off at each β-oxidation can combine with each other or with acetic acid and form acetoacetic acid. The β-oxidation theory postulates that the shortening of the fatty acid chain down to a fragment with four carbon atoms, which on oxidation will give acetoacetic acid, is the only source of this substance. This postulate can now no longer be accepted, and the β-oxidation theory must be slightly modified.

Recent work has shown that β-oxidation and condensation of the two-carbon-atom fragments take place.[1] Thus, palmitic acid (16 carbon atoms) splits into eight molecules of a two-carbon-atom substance, which on combining give four molecules of acetoacetic acid.

Enzyme systems. Semipurified enzymes that can oxidize fatty acids have been prepared. The system is a complex one; among the many factors which form it, adenosinephosphate, Mg^{++}, coenzyme I, and cytochrome c have been found. Oxidation is also accelerated by the addition of any one of the components of the tricarboxylic cycle, *e.g.*, fumaric, succinic, α-ketoglutaric acids, etc.[2] Oxidation of acetoacetic acid also takes place by the tricarboxylic cycle.

Experiments with isotopes. The utilization of isotopes to label substances has shown that fat stores are not static and inert accumulations, but rather that they are the site of a continuous interchange of substances. Fatty acids with a chain of less than 10 carbon atoms are not stored; they are either burned immediately or utilized in the synthesis of higher fatty acids. Other fatty acids are mostly stored and then gradually mobilized and burned. Fatty acids are changing continuously: they are dehydrogenated, disintegrated, lengthened, converted into other fatty acids, etc. Thus stearic acid can be converted into oleic or palmitic acid and vice versa.[3]

This method has also demonstrated how in the course of utilization of fatty acids their carbon atoms enter into the formation of ketone bodies and the components of the tricarboxylic cycle.

[1] MACKAY, E. M., *et al.*, *J. Biol. Chem.*, **135**, 157, 1940; **136**, 503, 1940; *J. Clin. Endocrinol.*, **3**, 101, 1943.

[3] SCHOENHEIMER, R., and D. RITTENBERG, *J. Biol Chem.*, **120**, 155, 1937.

These few examples show how the use of isotopes has given a solid base to our knowledge of the mechanism of fatty-acid oxidation.

The mechanism of fatty-acid oxidation. The process of fatty-acid oxidation is not yet known with any certainty. A plausible, but by no means final, interpretation of the facts is that oxidation proceeds along the path described by Knoop, *i.e.*, β-oxidation with release of 2-carbon fragments. The substrate oxidized would not, however, be free fatty acid but a compound of the latter with coenzyme A (acetyl-CoA). The 2-carbon fragment broken off would not be acetic acid but acetyl-CoA. Acetyl would then be oxidized in the tricarboxylic cycle or would combine with another acetyl to form acetoacetic acid (see tricarboxylic cycle page 319).

KETOGENESIS AND KETOLYSIS

Excessive accumulation of ketone bodies is called ketosis. In this condition the concentration of ketone bodies in the blood rises above the normal level, and ketonuria increases. Ketosis leads to acidosis; therefore it causes a decrease in the alkali reserve in plasma, hyperventilation and a low CO_2 tension in alveolar air, increase in urinary ammonia, and in advanced stages a low blood pH (uncompensated acidosis). In severe acidosis, with an alkali reserve of 25, 20, or less, the subject becomes comatose or is on the verge of coma (*e.g.*, diabetic coma) and dies if adequate treatment is not given.

In normal conditions ketone bodies are formed in the liver and are oxidized in the tissues. When an excessive amount of fat is catabolized, the organism cannot burn it at a sufficiently rapid rate and ketone bodies accumulate, causing ketosis. Excessive catabolism of fats is observed when the diet does not contain a sufficient amount of carbohydrate, or when the organism cannot utilize carbohydrate at the normal rate, as in diabetes (Hirschfeld, 1895). In these cases the tissues utilize fats instead of carbohydrate.

An increase of ketone bodies is observed in the following circumstances: (*a*) in complete fasting; (*b*) when there is excess fat and insufficient carbohydrate in the diet; (*c*) in severe diabetes; (*d*) following injection of anterior hypophyseal extract.

The liver is the principal, perhaps the only, organ where ketone bodies are formed, as is

demonstrated by the following observations: (*a*) a liver perfused with fatty acids and some amino acids forms ketone bodies (Embden); (*b*) when fatty acids are added to slices of surviving liver, ketone bodies form, but in similar conditions slices of other tissues do not produce ketone bodies; (*c*) direct analysis of the liver reveals a higher concentration of ketone bodies than in any other tissue;[1] (*d*) these bodies are found in higher concentration in blood leaving the liver than in blood entering it;[2] (*e*) in hepatectomized animals pancreatectomy[3] and the injection of anterior hypophyseal extract[4] are not followed by an increase in ketone bodies.

Ketone bodies formed in the liver are oxidized in the tissues, especially in the muscles, in both normal and diabetic animals. This can be demonstrated in eviscerated animals[5] and *in vitro*, adding ketone bodies to minced muscle tissue.[6] The heart also utilizes ketone bodies. Administration of glucose and insulin diminishes the formation of ketone bodies (ketogenesis) but does not modify their oxidation by the tissues (ketolysis).

Administration of carbohydrate diminishes ketonuria provoked by fasting or an excessively fat diet. Insulin rapidly diminishes ketonuria in diabetes, because it acts on the liver, increasing the utilization of carbohydrate and diminishing that of fat and therefore the formation of ketone bodies.

Up to quite recently the aphorism "fats burn in the flame of carbohydrates" (Rosenfeld, 1906) was accepted as stating a well-proved fact. Later it was shown that the tissues of normal and diabetic animals utilize ketone bodies, a process that is not modified by the addition of glucose or insulin; therefore carbohydrate utilization does not increase ketolysis (destruction of acetoacetic acid) but diminishes hepatic ketogenesis. According to Stadie, acetoacetic acid is completely burned as long as the utilization of fats does not exceed a certain rate and no ketone bodies are excreted, but if fats are utilized at a higher rate, the amount of ketone bodies exceeds the capacity of the tissue to burn them, and the excess is accumulated and excreted into the urine. It is usually accepted now that the liver utilizes carbohydrate in preference to fat, so normally the amount of ketone bodies formed does not exceed the capacity of the tissues to burn them, and there is little or no ketonuria. When the liver has not enough carbohydrate at its disposal, or when its power of utilizing carbohydrate is diminished, it oxidizes fats and forms ketone bodies, thus increasing ketonemia and ketonuria.

Extirpation of the hypophysis or of the adrenals diminishes ketonuria in normal and diabetic animals, probably because these operations diminish protein and fat catabolism. Hyperthyroidism, on the contrary, increases ketogenesis in carbohydrate fasting and in diabetes. Anterior hypophyseal extract and some of the corticoadrenal hormones increase ketogenesis and ketonuria.

The Metabolism of Sterols

The metabolism of fats and phospholipids is closely related to that of sterols, which are not lipids. Cholesterol is an alcohol in which the hydroxyl is combined to a cyclopentanoperhydrophenathrene ring, which has side chains.

The term "steroid" is used for a large group of substances chemically related to the sterols by the nature of the constituent nucleus. This group includes, beside the sterols, the D vitamins, bile acids, sexual and corticoadrenal hormones, saponins, the glucosides of digitalis, substances in toad venom, carcinogenic substances, some of the "organizers" in the embryo, etc. These substances are of great biologic importance.

Sterols are essential constituents of cells. Apparently there is a chemical and functional equilibrium between sterols and lipids. There are also sterols in the blood, bile, and other organic fluids. They exist in the free state and combined with fatty acids as esters; usually there is a fixed ratio between these two states. The sterols are in the free state in bile, and in the erythrocytes and brain tissue they are mainly in the free state. In blood plasma, on the other hand, more than half the sterols are combined in esters

The sterol most commonly found in the animal organism is cholesterol, which on losing hydrogen acquires a second double bond and is converted into dehydrocholesterol (a provitamin

which exists in the tissues) or into coprosterol found in the feces. Stigmasterol is the most abundant sterol in plants and ergosterol in fungi.

Absorption. Cholesterol and the D vitamins are the only sterols readily absorbed from the intestine. Cholesterol is not well absorbed unless fat is being absorbed simultaneously. Plant sterols, including ergosterol, are absorbed only in very small amounts. Bile, through its hydrotropic effect, helps the absorption of the D vitamins and probably also of cholesterol. Free cholesterol and cholesterol esters increase in the erythrocytes and blood plasma during absorption.

Nevertheless cholesterol synthesis proceeds at about one-third the rate of fatty-acid synthesis. A diet with abundant fat increases the synthesis of cholesterol.[1] Acetic acid is utilized in the synthesis of cholesterol by surviving slices of liver[2] when it is added to the substrate directly or can be split off from pyruvate, isovalerate, hexanate, octanate, or acetylacetate.

Intermediary metabolism and destruction. The intermediary metabolism of sterols is not well known. Generally, parallel changes in the concentration of sterols and fat in the blood and tissues are observed, but in some cases fat and sterols vary independently.

(*a*) (*b*)
Sterols: *a*, cholesterol; *b*, ergosterol.

Origin. Cholesterol has an endogenous and exogenous origin. Exogenous cholesterol is ingested with foods, particularly in eggs, brains, and liver. Endogenous cholesterol is the product of synthesis by the tissues. The existence of this synthesis has been demonstrated repeatedly, but its chemical process is still unknown. Larger amounts of cholesterol are found by measuring the cholesterol content of the body than can be accounted for by the cholesterol ingested[1] in animals fed on a diet poor in cholesterol. In mice fed a cholesterol-free diet and "heavy" water (*i.e.*, water in which hydrogen is replaced by deuterium), cholesterol with deuterium in its molecule has been found; an amount of cholesterol equivalent to that existing in the whole body of the animal at the beginning of the experiment can be synthesized in 1 month.[2]

[1] Channon, H. S., *Biochem. J.*, **19**, 424, 1925.

[2] Rittenberg, D., and R. Schoenheimer, *J. Biol. Chem.*, **121**, 235, 1937.

Destruction of cholesterol in the organism has been demonstrated in birds, rabbits, and mice. A mouse fed on a diet containing large quantities of cholesterol can destroy in 1 month five times the amount existing in the whole body at the beginning of the experiment.[3] The destruction of sexual steroids by the liver has been well demonstrated and some of the end products are known; *e.g.*, some of the testicular and corticoadrenal steroids give rise to 17-ketosteroids which are excreted in the urine.

Excretion. Cholesterol and its derivatives are excreted (*a*) in the bile, as free cholesterol, part of which is reabsorbed from the intestine; (*b*) through the mucosa of the large intestine,

[1] Eckstein, H. C., *J. Biol. Chem.*, **125**, 99 and 107, 1938.

[2] Bloch *et al.*, *J. Biol. Chem.*, **162**, 441, 1946; **107**, 811, 1948.

[3] Schoenheimer, R., and F. Breusch, *J. Biol. Chem.*, **103**, 439, 1933.

which excretes dehydrocholesterol and coprosterol. There is no cholesterol in normal urine, but it is found in cases in which there is infiltration of the renal tubes by cholesterol deposits (lipoid nephrosis).

Functions. Cholesterol seems to play some part in the following processes: (*a*) in the absorption and transport of fats; (*b*) in the permeability of cell membranes (therefore, in the interchange of water and substances in solution); (*c*) in the isolation of the nerve impulse (cholesterol in the neural sheaths); (*d*) in the neutralization of hemolytic and cytolytic substances, such as saponins and phospholipid derivatives (lysocitin and lysocephalin)—an effect that has fostered the mistaken belief that it has universal antitoxic properties. Cholesterol is a precursor in the synthesis of bile acids and of sexual and corticoadrenal hormones. Dehydrocholesterol and irradiated ergosterol are converted into the antirachitic D vitamins.

A diet containing an excess of cholesterol provokes in certain species a fatty liver in which the formation and destruction of phospholipids are diminished. An excess of biotin in the diet produces infiltration of fat and cholesterol in the liver, which can be prevented by an adequate dose of inositol.

In the rabbit (Anitschkow) and guinea pig and in birds, cholesterol feeding provokes hypercholesterolemia with deposition of cholesterol in the arterial walls, which show lesions similar to those of atherosclerosis. Giant lipoprotein molecules appear in the serum; they have a high molecular weight, but owing to their large fat component they have a low specific gravity. They can be separated by fractionated ultracentrifugation, and the "atherosclerogenous band" (Sf 12 to 100) differs from the normal (Sf 10 or less) (Gofman *et al.*).

Lipoid thesaurismosis (lipoidosis). Abnormal storage of fat is observed in several diseases. Cholesterol and its esters are deposited in the following conditions: (*a*) localized or generalized xanthomatosis: (*b*) diabetic xanthomatosis; (*c*) Hand-Schüller-Christian disease, in which yellow nodules are formed in the bones. In this last condition there is also polyuria, exophthalmos, etc. Deposition of phospholipids in the spleen, liver, and brain is observed in Niemann-Pick disease; sphyngomyelin is particularly increased. Cerebrosides are accumulated in Gaucher's disease, in which the spleen is enlarged, there is thrombopenia, and radiographs show maculae in the bones; large amounts of kerasin are formed in this disease.

CHAPTER 43

Protein Metabolism

CONSTITUTION OF PROTEINS

Protein is an essential constituent of protoplasm in all living organisms. It differs from carbohydrate and fat because it is made up not only of carbon, oxygen, and hydrogen, but also of nitrogen, sulfur, and in certain cases phosphorus. The average elementary composition of protein (globulins and albumins) is as follows: C, 54 per cent; H, 7 per cent; O, 22 per cent; N, 16 per cent; S, 1 per cent. Therefore 1 gm. of protein has 0.16 gm. of N, and 1 gm. of protein N is the equivalent of 6.25 gm. of protein. Conjugated proteins are those in whose molecule a nonprotein group, called in some cases the prosthetic group, is joined to a protein group; *e.g.*, hemoglobin, glycoproteins, lipoproteins, and nucleoproteins.

Proteins are made up of numerous units or "building stones," known as amino acids. Protein metabolism is mainly the metabolism of amino acids. Proteins are of great but variable molecular weight, *e.g.*, 66,400 for hemoglobin, 5,000,000 for hemocyanin.

Natural amino acids are fatty acids in which one of the alpha hydrogen atoms has been replaced by an NH_2 group. Therefore an amino acid has a basic (NH_2) group and an acid (COOH) group. The simplest amino acid is glycine (also called glycocoll), which is aminoacetic acid. The next one is alanine (α-aminopropionic acid). With the exception of proline and oxyproline, in which there is an NH group in the ring, amino acids can be represented by formulas of the following type, in which R represents the rest of the amino-acid molecule:

$$\begin{array}{c} NH_2 \\ | \\ R \cdot CH \cdot COOH \end{array}$$

For example:

$$\underset{\text{Glycine}}{\begin{array}{l} NH_2 \\ | \\ CH_2COOH \end{array}} \qquad \underset{\text{Alanine}}{\begin{array}{c} NH_2 \\ | \\ CH_3 \cdot CH \cdot COOH \end{array}}$$
The basic group of one amino acid may combine with the acid group of another, with loss of water:

$$\underset{\text{Alanine}}{CH_3 \cdot CHNH_2 \cdot CO}\boxed{OH + H}\underset{\text{Glycine}}{NHCH_2 \cdot COOH} \rightarrow \underset{\text{Alanylglycine}}{CH_3 \cdot CHNH_2 \cdot CO \cdot NHCH_2 \cdot COOH} + H_2O$$
The union CO—NH is known as a peptide linkage. The reverse process, which also takes place in the peptide linkage, causes the separation of amino acids; it is a process of hydrolysis.

$$\underset{\text{Alanylglycine}}{CH_3 \cdot CHNH_2CONH \cdot CH_2COOH} + H_2O \rightarrow \underset{\text{Alanine}}{CH_3 \cdot CHNH_2 \cdot COOH} + \underset{\text{Glycine}}{CH_2NH_2 \cdot COOH}$$
In theory the natural amino acids could form an enormous number of proteins, but there is evidence that this is not so. Amino acids seem to be distributed in the polypeptide chain in a certain order peculiar to each protein.

Theoretically there are two stereoisomers for each amino acid, but with the exception of threonine, all natural amino acids are the L and not the D isomers.

The architecture of the protein molecule has been studied by means of x-ray diffraction photographs (Astbury), and several optical methods. Fibrous proteins, such as keratin, collagen, and myosin, have long threadlike molecules. These filaments can be stretched, and afterward recover their initial length. The mole-

cule changes in length by processes of folding and unfolding, similar to a concertina when it is being played. Globular proteins, *e.g.*, blood plasma proteins and egg albumen, are formed by chains or filaments wound in a compact mass.

Proteins form colloidal solutions because of the large size of their molecules. Proteins and amino acids are ampholytes, because the acid group (COOH) can set free H^+ and the basic group (NH_2) can accept H^+ or set free $OH-$ from H_2O. In an acid medium proteins behave as bases, and in alkaline medium they behave as acids, forming salts (proteinates) such as sodium or potassium proteinate. At a certain hydrogen ion concentration of the solvent, the protein molecule is electrically neutral, its dissociation is at a minimum, and the concentration of acid ions is equal to that of basic ions. This is known as the isoelectric point. The charge, solubility, stability, and viscosity of the majority of proteins are at a minimum when they are in a solvent at the isoelectric point; some of them precipitate. Isoelectric precipitation is used to separate and purify proteins.

CLASSIFICATION OF THE AMINO ACIDS

I. Aliphatic amino acids

A. *Monoaminomonocarboxylic acids*

1. Glycine (or glycocoll) $C_2H_5NO_2$, aminoacetic acid:
$$\begin{array}{l} NH_2 \\ | \\ CH_2\cdot COOH \end{array}$$

2. Alanine $C_3H_7NO_2$, α-aminopropionic acid:

$$\begin{array}{l} \quad\ NH_2 \\ \quad\ \ | \\ CH_3\cdot CH\cdot COOH \end{array}$$

3. Serine $C_3H_7NO_3$, β-hydroxy-α-aminopropionic acid.

$$\begin{array}{l} \qquad\quad NH_2 \\ \qquad\quad\ | \\ CH_2OH\cdot CH\cdot COOH \end{array}$$

4. Threonine $C_4H_9NO_3$, α-amino-β-hydroxybutyric acid:

$$\begin{array}{l} \qquad\qquad\ NH_2 \\ \qquad\qquad\ \ | \\ CH_3\cdot CHOH\cdot CH\cdot COOH \end{array}$$
5. Valine $C_5H_{11}NO_2$, α-aminoisovalerianic acid:
$$\begin{array}{l} CH_3 \quad NH_2 \\ \quad \diagdown \quad\ | \\ \qquad CH\cdot CH\cdot COOH \\ \quad \diagup \\ CH_3 \end{array}$$

6. Norleucine $C_6H_{13}NO_2$, α-aminocaproic acid:

$$\begin{array}{r} NH_2 \qquad\quad \\ | \qquad\qquad \\ CH_3\cdot CH_2\cdot CH_2\cdot CH_2\cdot CH\cdot COOH \end{array}$$

7. Leucine $C_6H_{13}NO_2$, α-aminoisocaproic acid:

$$\begin{array}{l} CH_3 \qquad\quad NH_2 \\ \quad \diagdown \qquad\quad | \\ \qquad CH\cdot CH_2CH\cdot COOH \\ \quad \diagup \\ CH_3 \end{array}$$

8. Isoleucine $C_6H_{13}NO_2$, β-methyl-β-ethyl-α-aminopropionic acid:

$$\begin{array}{l} \quad CH_3 \quad NH_2 \\ \qquad \diagdown \quad\ | \\ \qquad\quad CH\cdot CH\cdot COOH \\ \qquad \diagup \\ CH_3\cdot CH_2 \end{array}$$
B. *Monoaminodicarboxylic acids*

9. Aspartic acid $C_4H_7NO_4$, α-aminosuccinic acid:

$$\begin{array}{r} NH_2 \qquad\quad \\ | \qquad\qquad \\ COOH\cdot CH_2\cdot CH\cdot COOH \end{array}$$
10. Glutamic acid $C_5H_9NO_4$, α-aminoglutaric acid:

$$\begin{array}{r} NH_2 \qquad\quad \\ | \qquad\qquad \\ COOH\cdot CH_2\cdot CH_2\cdot CH\cdot COOH \end{array}$$
C. *Diaminomonocarboxylic acids*

11. Arginine $C_6H_{14}N_4O_2$, δ-guanidine-α aminovalerianic acid:

$$\begin{array}{l} \qquad NH_2 \qquad\qquad\qquad\qquad NH_2 \\ \qquad\ | \qquad\qquad\qquad\qquad\qquad | \\ NH{=}C\cdot NH\cdot CH_2\cdot CH_2\cdot CH_2\cdot CH\cdot COOH \end{array}$$

12. Lysine $C_6H_{14}N_2O_2$, α-ϵ-diaminocaproic acid:

$$\begin{array}{l} NH_2 \qquad\qquad\qquad\quad NH_2 \\ | \qquad\qquad\qquad\qquad\quad | \\ CH\cdot CH_2\cdot CH_2\cdot CH_2\cdot CH\cdot COOH \end{array}$$

D. *Sulfur-containing amino acids*

13. Cystine (or dicysteine) $C_6H_{12}N_2S_2O_4$, di-β-thio-α-aminopropionic acid:

```
    NH2                NH2
    |                  |
COOH·CH·CH2·S·S·CH2·CH·COOH
```
14. Methionine $C_5H_{11}SNO_2$, α-amino-γ-methylthio-*n*-butyric acid:

```
                  NH2
                  |
CH3—S—CH2·CH2·CH·COOH
```

II. Aromatic amino acids

15. Phenylalanine $C_9H_{11}NO_2$, β-phenyl-α-aminopropionic acid:

```
    H  H
    C=C         NH2
   /   \        |
HC      C·CH2·CH·COOH
   \\  //
    C—C
    H  H
```

16. Tyrosine $C_9H_{11}NO_3$, β-parahydroxyphenyl-α-propionic acid:

```
     H  H
     C=C         NH2
    /   \        |
HOC      C·CH2·CH·COOH
    \\  //
     C—C
     H  H
```
III. Heterocyclic amino acids

17. Tryptophane $C_{11}H_{12}N_2O_2$, β-indole-α-aminopropionic acid:

```
    H
    C              NH2
  //  \            |
HC     C——————C·CH2·CH·COOH
 |     ||     ||
HC     C      CH
  \\  /  \   /
    C      N
    H      H
```

Indole nucleus
18. Histidine $C_6H_9N_3O_2$, α-amino-β-imidazolpropionic acid:

```
                 NH2
                 |
HC════C·CH2·CH·COOH
|       |
N       NH
  \\   /
    C
    H
```

Imidazol ring
19. Proline $C_5H_9NO_2$, pyrrolidinecarboxylic acid:

```
H2C——————CH2
 |        |
H2C      CH·COOH
   \    /
     N
     H
```

Pyrrole nucleus
20. Hydroxyproline (or oxyproline) $C_5H_9NO_3$, γ-hydroxy-α-pyrrolidinecarboxylic acid:

```
  H
HOC——————CH2
 |        |
H2C      CH·COOH
   \    /
     N
     H
```
This list of amino acids found in animal organisms is completed by the addition of 3-5-diiodotyrosine (or iodogorgoric acid), thyroxine, citruline, ornithine, and a few others.

ABSORPTION OF PROTEIN

The process of digestion hydrolyzes proteins into the constituent amino acids, which are then absorbed in the small intestine. Amino acids are simple diffusible substances, the "building stones" that the organism will use to reconstruct its own large specific protein molecules. Proteins have the ability to produce immunologic reactions that are species-specific. Amino acids do not produce any immunologic reactions.

Native proteins are not usually absorbed. In certain conditions, however, particularly in young animals, very small amounts can be absorbed. This should be considered more a deficiency in digestion than a normal process. When a protein from another species enters into the circulation, it acts as a foreign body and pro-

vokes the formation of antibodies. The organism becomes sensitized; after one to three weeks it is allergic to the protein, and may respond with an anaphylactic shock to another dose of it.

Specific precipitins for the protein in question are usually found in the subject's serum. Foreign proteins are toxic; the reactions they provoke are usually transitory, but if the administration is prolonged cachexia and death may result (protein intoxication). In man, injection of blood serum from another species frequently causes what is known as serum sickness; this begins a few days after the injection with a nettle rash (urticaria) or cutaneous erythema, painful joints, edema, fever, etc. An acquired capacity to react to foreign proteins is revealed by food idiosyncrasies, hay fever, asthma, and other abnormal reactions to protein in food, fungi, pollen, etc.

Several workers have reported the absorption of small amounts of polypeptides in the course of digestion,[1] but only insignificant amounts of protein food are absorbed in this form. Nearly all protein is absorbed in the form of amino acids. Blood normally contains amino acids (5 to 8 mg. of amino-acid nitrogen in 100 ml. of blood, in fasting subjects), which are in a free state, as is demonstrated by dialyzing circulating blood (Abel's vividiffusion technique) and by paper chromatography (Dent). In the tissues they are found in a slightly higher concentration. In the course of digestion, amino-acid concentration increases in the blood of the portal and jugular veins,[2] especially essential amino acids of high molecular weight. At the same time there is an increase in the urinary excretion of amino acids, especially of nonessential amino acids of low molecular weight. Human blood plasma given by mouth is absorbed and its nitrogen is utilized by the organism; its absorption, however, is not accompanied by an increase in amino acids in the blood.

Amino acids in the tissues also increase during absorption, especially in the liver, muscles, and kidneys. The liver is the tissue that takes up amino acids at the highest rate and then rapidly deaminizes them, producing urea, which increases in the blood during absorption of protein.

[1] London, E. S., and N. Kotschneff, *Ztschr. f. physiol. Chem.*, **228**, 235, 1934; Godfried, *Biochem. J.*, **33**, 955, 1939.

[2] Van Slyke, D. D., and G. M. Mayer, *J. Biol. Chem.*, **16**, 197 and 213, 1913; Van Slyke, D. D., *Science*, **95**, 259. 1942; Dent, C. E., *Biochem. Symposia*, **3**, 25, 1949.

An important, although indirect, demonstration that amino acids are the nutritional basis of protein metabolism was given by Rose, when he showed that normal growth can be maintained by the administration of a mixture of 10 amino acids as the only source of nitrogen. That nitrogen equilibrium can be maintained by the ingestion[1] or injection[2] of abiuretic products of protein digestion is a fact that has been known for a long time.

PROTEIN BALANCE

Protein in food is broken down by digestion to amino acids, which are absorbed and utilized in the formation of the proteins specific for each animal and for each tissue (protein anabolism). At the same time protein and amino acids are being disintegrated and converted into other substances (protein catabolism). The greater part of the end products of protein catabolism is eliminated in the urine as nitrogenous substances; a small part is excreted in the feces. Fecal nitrogen is mostly nitrogen of foodstuffs that have not been absorbed. The rest, about 1 gm. per day (0.5 to 1.5 gm.), is nitrogen in the intestinal flora. Only a small part comes from the residue of digestive juices and cells shed by the intestinal mucosa. An insignificant amount of nitrogen is eliminated in the sweat—about 0.1 mg. daily (Benedict). Small quantities are lost when hair and nails are cut, in cutaneous desquamation, and in other secretions. Gaseous nitrogen is not fixed by the animal organism, and it plays no part in its metabolism.

If the intake of nitrogen is greater than the output, nitrogen is gained and it is said there is a positive balance. This occurs during growth, in pregnancy, in the development of muscle tissue by muscular exercise, and in convalescence after wasting disease. If the output of nitrogen is greater than the intake, there is loss of nitrogen and it is said there is a negative balance. This occurs in undernourishment, inanition, and cases of excess protein catabolism such as in fever, after accidental trauma or surgical operations, and in wasting diseases. In these cases nitrogen loss is compensated with difficulty; if

[1] Loewi, 1902; Henderson and Dean, 1903; Abderhalden *et al.*, 1907 to 1913. Enzymatic hydrolysis does not destroy the essential amino acids; acid hydrolysis destroys some of them.

[2] Henriques and Hansen, 1905; Henriques and Andersen. 1913.

the patient cannot ingest, digest, or absorb proteins, it is advisable to inject amino-acid solutions.[1] During the period of convalescence a positive nitrogen balance is established, and later the subject returns to nitrogen equilibrium.

A nursing mother may have a negative nitrogen balance because of nitrogenous substances secreted in the milk, but she maintains her own body proteins intact if she is adequately fed.

The adult organism in nitrogen equilibrium utilizes protein in preference to other substances, but it is not stored as is the case with fat and carbohydrate. In the 12 to 24 hr. following the administration of protein or amino acids, an equivalent amount of nitrogen is excreted in the urine. If the subject receives 10 gm. of protein nitrogen, he will eliminate 10 gm. of nitrogen in the urine; if 20 gm. is given him, 20 gm. will be eliminated. Nitrogen is retained in the organism only when there is a positive nitrogen balance, *i.e.*, in the circumstances mentioned in the preceding paragraph.

Observation of protein balance shows the nutritive value of the different proteins in the maintenance of nitrogen equilibrium, growth, and the repair of tissues.

PROTEIN REQUIREMENT

The protein in food is needed for growth and repair of tissues and for the maintenance of body proteins and body weight, because protein is being continuously catabolized. In the course of protein catabolism, for every gram of protein converted in the organism, 4.1 kg.-cal. is set free.

Protein deficiency delays or stops growth and causes loss of weight. The normal wear and tear of tissues is not repaired, *e.g.*, blood plasma and hemoglobin are not replaced. The healing of wounds is retarded, and resistance to trauma and infection is diminished. Fatty degeneration and cirrhosis of the liver can be prevented and sometimes cured by the administration of a sufficient amount of protein.

When all food is withheld (total fasting) or only protein is eliminated from an otherwise complete diet (protein fasting), the destruction of body protein does not cease, and nitrogenous end products of protein catabolism are still eliminated in the urine and feces. Nitrogen excretion diminishes, nevertheless, and after a 31- to 38-day fast it has been observed to fall to 6.9 and 3.3 gm. per day, whereas a normal, well-fed adult eliminates from 12 to 16 gm. daily. In protein fasting less nitrogen is eliminated than in total fasting; ingestion of carbohydrate and fat diminishes the amount of protein metabolized, and excretion of nitrogen is reduced to 3.8 gm. and even to 1.75 gm. daily. Protein is thus spared by the utilization of other nutritive substances. Protein sparing is greater if carbohydrate alone is ingested than if fat alone is ingested; but maximum protein sparing is obtained by the ingestion of carbohydrate and fat in amounts of equal caloric value.

Some hormones (hypophyseal, thyroid, testicular, etc.) are necessary during certain periods of life to maintain growth and protein anabolism. Extirpation of the anterior hypophysis or of the thyroid stops growth, and the formation of protein ceases almost completely. The administration of anterior hypophyseal extract or the growth hormone (somatotrophin), and of testosterone provokes the retention of nitrogen and increases the formation of protein. On the other hand excess thyroid secretion and some of the corticoadrenal hormones increase protein catabolism and therefore nitrogen excretion (see Chap. 53, The Thyroid Gland, and Chap. 54, The Adrenal Glands).

The minimum physiologic protein requirement is the smallest amount of protein needed to maintain nitrogen equilibrium. To determine this minimum the subject is given a protein-free but otherwise complete diet, and then increasing quantities of protein are given until nitrogen equilibrium is obtained. The minimum varies in different subjects and according to the experimental conditions. Figures given in the numerous publications on the subject vary from ⅓ to ⅔ gm. of protein per kilogram of body weight per day. The average of several experiments by different workers has been given at 0.0548 gm. of N, corresponding to 0.34 gm. of protein per kilogram per day.[1] Sherman gives figures from 21 to 65 gm. (average 44.4 gm.) of protein per day, which corresponds approximately to 0.66 gm. per kg. per day.

According to Berg[2] many factors influence protein catabolism. In the first place habit is important; thus

[1] Peters, J. P., *et al.*, Seminar on Protein Hydrolysates, *Am. J. Med.*, **5**, 1948.

[1] Bertram, F., and A. Bornstein, in Bethe's "Handbuch der normalen und pathologischen Physiologie," **5**, 84, Springer, Berlin, 1928.

[2] Berg, O., "Eiweissbedarf und Mineralstoffwechsel bei einfachster Ernährung," S. Hirzel, Leipzig, 1931.

a herbivorous subject utilizes a vegetable diet, and a carnivorous one a meat diet, better than other diets, owing to a special adaptation of the digestive tract and metabolism. Nitrogen excretion is dependent on the ratio of base to mineral acids formed by the metabolization of the diet. If there is an excess of acid end products and the urine is acid, more nitrogen is excreted than if base is predominant. Base is ingested in the food, and mineral acids are mostly end products of protein metabolism.

The standard minimum protein requirement is the smallest amount of protein needed to maintain optimum conditions of health. It is very difficult to say what this minimum is for man. Careful observations made on human subjects have shown that it is possible to keep in excellent health with small amounts, *e.g.*, 40 to 50 gm. daily (Chittenden), 35 gm. (Sherman), and even 22 gm. (Hinhede). It is usually accepted that protein intake should not fall below 1 gm. per kg. of body weight per day; half the protein should be of first-class biologic value, *i.e.*, animal protein (milk, eggs, meat, glands such as liver and kidney). These amounts are probably more than twice the minimum physiologic protein requirement of the majority of individuals. They assure, however, a margin of safety, especially important in the prevention of insufficiencies due to the ingestion of poor-quality protein.

Man can live in excellent health on an almost exclusively meat diet. Krogh has observed a 35- to 85-gm. daily nitrogen excretion in Eskimos (this corresponds to a daily catabolism of up to 530 gm. protein). Argentine cattle drovers were accustomed to eat regularly 2 to 3 kg. of meat daily.

In recent years, the great importance of protein deficiency in the diet has been well demonstrated and understood. The effects of protein deficiency and the means of preventing it have been carefully studied. It has also been shown that men fed a high-protein diet are of greater height and weight than others, of the same race, fed on a lower protein diet.

Protein deficiency is due to (*a*) insufficient protein in the diet, with respect to either quantity or quality; (*b*) disturbances in digestion or absorption of protein (*e.g.*, enteritis, diarrhea, etc.); (*c*) insufficient protein synthesis by the organism (*e.g.*, certain forms of hepatic insufficiency); (*d*) increase in protein requirement not covered by the diet (growth, pregnancy, lactation); (*e*) excess protein destruction due to trauma or disease (burns, accidental trauma, surgical operations, fever, severe diabetes, wasting disease, infections, etc.); (*f*) abnormal loss of protein (burns, albuminuria, hemorrhage, frequent evacuation of peritoneal or pleural effusions).

Loss of protein is made evident by a negative nitrogen balance. There is loss of body weight. Resistance to infection and trauma diminishes, and healing is delayed. The liver is easily damaged, and hepatic insufficiency occurs. There is hypoproteinemia, due especially to a decrease in serum albumin. Marked hypoproteinemia is accompanied by edema. Elman has calculated that for each gram of plasma protein lost there is a corresponding loss of about 30 gm. of tissue protein.

Protein deficiency is remedied by increasing the protein in the diet or, when protein cannot be digested, by injecting protein hydrolysate. In certain serious preoperative or postoperative conditions and in cases of severe malnutrition, protein equilibrium has been maintained by transfusion of blood or plasma, this being the only source of nitrogen. Nitrogen equilibrium has also been maintained by injecting solutions of amino acids containing the "essential" amino acids or of casein hydrolysate.[1]

The maintenance of nitrogen equilibrium for a short time does not signify that protein is being synthesized. For this to occur, nitrogen, phosphorus, and potassium must be accumulated, and the increase in weight observed must not be due solely to retention of water.[2]

THE BIOLOGIC VALUE OF PROTEINS

The biologic value of a protein depends on (*a*) its digestibility; (*b*) its adequacy in providing material for the formation of body protein necessary for the maintenance of nitrogen equilibrium or for growth.

The digestibility of a protein is measured by the proportion of the amount ingested that is absorbed. This measurement is carried out as follows: The amount of nitrogen in the food is determined. Then the fecal nitrogen is deter-

[1] ELMAN, R., *J. A. M. A.*, **128**, 659, 1945; *Advances in Protein Chemistry*, **3**, 269, 1947; "Parenteral Alimentation in Surgery with Protein and Amino Acids," Hoeber, New York, 1947.

[2] MOORE, F. D., *Nutrition Rev.*, **6**, 161. 1948.

mined and subtracted from the former.[1] The difference corresponds to nitrogen absorbed. Thus if, out of 100 gm. of ingested protein, 95 gm. is absorbed, digestibility is said to be 95 per cent. Digestibility of animal proteins is above 95 per cent; that of potatoes and other vegetables is about 80 per cent.

* Percentage of essential amino acids.

The biologic value of a protein is determined by giving the subiect a protein-free, but otherwise complete, diet, to which the protein to be studied is added in variable amounts (Osborne and Mendel). The growth value is usually expressed in grams of weight increase per gram of protein given. The maintenance value is expressed by the minimum amount ingested (per gram of body weight per week) that maintains a stable body weight. Mitchell expresses the maintenance or growth value of a protein by the percentage of nitrogen retained in the body.

In man several means have been used to calculate the biologic value of proteins (Table 49).

[1] The fasting subject eliminates 0.5 to 1.5 gm. of nitrogen in the feces; therefore from the total fecal nitrogen 1 gm. is deducted.

Thomas[1] determined the amount of body protein spared, in human subjects on a protein-free diet, by the ingestion of the protein studied. Milk was considered the standard and given a value of 100; others take whole egg as the standard. He found that animal proteins are far superior to vegetable proteins in this respect. Other workers have not observed such great differences.

Complete and incomplete proteins. Osborne and Mendel's work[2] has shown there are some proteins by which growth can be maintained, others by which body weight is maintained but with which growth ceases, and others with which weight is lost and the animal cannot live. The two latter are known as incomplete proteins. Their deficiency in respect of nutritive properties is due to the fact that certain amino acids do not form part of their molecule. Thus gelatin does not contain tryptophan, cystine, valine, or phenylalanine; if these amino acids are added to a diet of which the only protein is gelatin, the animals grow normally. Another typical example is given by zein (the protein in corn), which does not contain tryptophane or lysine. Growth and weight are not maintained in animals when zein is the only protein in the diet. On adding tryptophane to the zein, the animals do not lose weight, but they do not grow. If both tryptophane and lysine are added to zein, a normal growth curve is obtained (Fig. 204).

Essential amino acids. Rose[3] and his associates have done important work on the amino acids needed for normal nutrition. They fed animals with various mixtures of the 22 amino acids that form part of natural proteins, these being the only source of nitrogen the animals had. They proved that ten amino acids were essential for normal growth in the rat. Twelve were not essential (Table 50). The essential ones are not synthesized in the organism at a sufficiently rapid rate for normal growth. Only eight of these amino acids seem to be indispensable in man.[4] Histidine and arginine are necessary for the rat, but it has not been definitely established that they are essential in human

nutrition.[1] Ten amino acids are not indispensable for the rat or man.

When an essential amino acid is omitted from the diet, there is a negative nitrogen balance, with loss of appetite, and the subject feels tired and irritable. On adding the amino acid to the diet, these signs and symptoms disappear. Observations in man have been made over only short periods, and the effect of amino-acid insufficiency on several functions, such as growth, has not been examined.

The amino-acid mixtures which have so far been prepared are less efficient than native proteins. Block and Bolling consider there are four "semi-indispensable" amino acids: (*a*) arginine and glycine, which are synthesized in the body, but at an insufficient rate to maintain maximum growth; (*b*) cystine and tyrosine, which are indispensable when there are insufficient amounts of methionine and phenylalanine respectively.
FIG. 204. Growth curves of rats fed on a basic diet to which different proteins were added. Ordinate, weight in grams. Curve I (casein) corresponds to normal growth. (*Osborne, T. B., and L. B. Mendel, J. Biol. Chem., vol. 17, p. 325, 1914.*)

Table 50. Essential and Nonessential Amino Acids

Essential amino acids				Nonessential amino acids for the rat and man
Name	*For the rat*	*For man, gm. per day*		
		Minimum	*Advisable*	
L-Tryptophane	+	0.25	0.50	L-Alanine
L-Lysine	+	0.80	1.60	L-Aspartic acid
L-Methionine	+	1.10	2.20	L-Citrulline
L-Valine	+	0.80	1.60	L-Glycine
L-Leucine	+	1.10	2.20	L-Glutamic acid
L-Isoleucine	+	0.70	1.40	L-Cystine†
L-Phenylalanine	+	1.10	2.20	L-Hydroxyglutamic acid
L-Threonine	+	0.5	1.0	L-Hydroxyproline
L-Arginine*	+			L-Norleucine
L-Histidine*	+			L-Proline
				L-Serine
				L-Tyrosine‡

* Arginine is synthesized at an insufficient rate to assure normal growth in the rat; it is not essential for man. The dispensability of arginine and histidine, however, is not unanimously accepted (Albanese).

† It can replace methionine in part, but not completely.

‡ It can replace phenylalanine in part, but not completely.

The amount of amino acids in foodstuffs has been determined; there are special tables with the corresponding figures. Also the amino-acid content of normal diets has been established (Table 51).

another protein that contains them. Thus on zein alone growth and weight cannot be maintained, however large the amount given (Fig. 204); neither can normal growth be obtained
Fig. 205. Growth curves of rats fed on a basic diet to which different proteins were added. Ordinate, weight in grams. In III an insufficient amount (4.5 per cent) of a complete protein—lactalbumin—supplements successfully an incomplete protein—zein. In IV the addition of cystine supplements an insufficient amount (9 per cent) of casein. (*Osborne, T. B., and L. B. Mendel, J. Biol. Chem., vol. 17, p. 325, 1914.*)

when the diet contains less than 8 or 9 per cent lactalbumin as the only protein. Nevertheless, a diet containing 13.5 per cent zein supplemented with 4.5 per cent lactalbumin assures normal growth, because the small amount of lactalbumin supplements the deficiencies of zein (Fig. 205). In corn grain, zein is supplemented by glutelin, a complete protein which contains the amino acids missing in the former.

Supplementary relations between proteins. An incomplete protein, which by itself cannot serve to maintain growth and life, can nevertheless be used in nutrition if the missing amino acids are added to it, or if it is associated with

Table 51. Amino Acids in Grams per Day in Normal Diets of Adults

Amino acids	*American diets*		*French diet, Randoin and Fournier*
	Macy	*Block*	
* Valine	3.2	3.9	4.2
* Leucine	9.6	12.6	8.6
* Isoleucine	3.1	3.7	3.8

* Methionine	3.7	4.1	4.3
* Lysine	4.6	5.2	3.8
* Phenylalanine	4.2	4.7	4.5
* Tryptophane	0.9	1.1	0.9
Histidine	1.6	2.0	2.2
Arginine	4.7	4.7	4.3
Tyrosine	3.9	3.9	3.8

* Essential amino acids.

A diet should contain several proteins, especially if it is a vegetarian diet. If only a small amount of protein can be given, it should be an animal protein of high biologic value. A mixed diet should contain the proteins of eggs, milk, liver or kidney, meat, potato, wheat, oats, corn, or beans (these have been given in decreasing order of nutritive value).

SPECIFIC DYNAMIC ACTION

During the absorption of food there is an increase in the metabolic rate, known as the "specific dynamic action" (SDA) of food. For every 100 cal. produced in basal conditions, 130 cal. is produced if the subject has ingested the equivalent of 100 cal. of meat protein. If the equivalent of 100 cal. of carbohydrate is ingested, 104 cal. will be produced, and 106 cal.

for every 100 cal. of fat. These are only approximate values, which vary from one experiment to another. The extra energy produced by the ingestion of protein cannot be converted into mechanical or other forms of energy; it is lost as heat. Specific dynamic action can be observed only in subjects kept at an environmental temperature of 30°C.; if the animals are at a temperature that stimulates heat production for the maintenance of the body temperature (see Chap. 48), the extra heat of SDA is incorporated into the heat used for body-temperature regulation.

The specific dynamic action of proteins is dependent on the process of deamination that takes place in the liver. Hepatectomy suppresses deamination and the SDA.[1] Six amino acids are responsible for the SDA of proteins. These are glycine, alanine, leucine, glutamic acid, tyrosine, and phenylalanine; the last of these is the most active (Rapport and Beard). The intensity of SDA produced by a protein depends on the percentage of these amino acids it contains.

SDA of proteins does not seem to depend on the utilization of the deaminated residue. Thus in a dog treated with phlorhizin, proteins and amino acid produce an SDA, although all the extra glucose formed is excreted in the urine (Lusk). It is not due to digestive activity, because it is not produced by stimulation of the secretions or motility of the digestive tract. Several hypotheses have been put forward to explain the mechanism of SDA. It is generally admitted to be due to the six amino acids mentioned, to the NH_2 group (Grafe), and to certain products of the intermediary metabolism of those acids.[2]

Lundsgaard[3] observed that the oxygen consumption of the perfused liver of a cat increased at the same rate as urea formation when amino acids or ammonium salts were added to the perfusion fluid. He concluded that the increase in O_2 consumption was due to mobilization of energy for the formation of urea.

SDA of fats has been attributed to fat plethora, and it lasts 10 to 12 hr. That of carbohydrate is also attributed to plethora, which increases glucose consumption and its conversion into glycogen.

[3] LUNDSGAARD, E., *Acta physiol. Scandinav.*, **4**, 330, 1942.

SDA is diminished in thyroid and hypophyseal insufficiencies in certain species; *e.g.*, it is diminished in hypophyseal insufficiency in man and rats, but not in dogs. This seems to be due not to a direct effect of hormonal insufficiencies on metabolism but to retarded intestinal absorption.

PROTEIN STORAGE

Carbohydrate and fat are stored in the organism, but there is no satisfactory demonstration of protein storage. The so-called "protein stores" are constituted mainly by plasma proteins and by labile protein in the cytoplasm of the cells of muscle, liver, lymphoid tissues, etc. In an emergency, such as fasting, protein catabolism increases and many cells release protein, but this is recovered on return to normal conditions. Thus, in conditions of stress adrenal hormones are secreted in excess and lympholysis, *i.e.*, disintegration of lymphocytes and lymphoid cells, takes place. Thyroid hormone seems to play a similar part in the rapid mobilization of muscle protein. Increase of body proteins observed in growth, or when muscles hypertrophy owing to exercise, or in pregnancy and lactation, or after a prolonged fast, or in convalescence cannot be considered as storage of proteins, but as an increase in body mass.

THE FATE OF AMINO ACIDS

After absorption amino acids undergo one of the following processes: (*a*) *deamination*, *i.e.*, separation of the NH_2 with the formation of nitrogenous catabolic end products such as urea and creatinine in mammals and uric acid in birds; (*b*) *transamination*, *i.e.*, passage of NH_2 from one amino acid to another compound; (*c*) *utilization of the deaminated residue*, which may be converted into glucose, acetoacetic acid, or other substances and subsequently metabolized; (*d*) *utilization in protein synthesis* (plasma and tissue proteins, hemoglobin, etc.).

The following are some of the methods that have been used in the study of amino-acid metabolism. (*a*) observation of growth, nitrogen balance, and general health of animals fed on diets in which certain amino acids are absent or have been added; (*b*) determination in blood and urine of products of amino-acid catabolism; (*c*) perfusion of isolated organs; (*d*) transformations undergone by amino acids in the presence of surviving slices of tissues (Krebs); (*e*) permanent fistulization of blood vessels

(London's angiostomy) by means of silver cannulas, so that blood can be obtained from the arteries or veins (renal vessels, portal and suprahepatic veins, etc.) of healthy unanesthetized animals, in order to determine the concentration (not the rate) at which different substances enter or leave the organ in question; (*f*) administration of amino acids "labeled" by isotopes, such as N^{15} and deuterium in the NH_2 group or C^{14} in the fatty-acid chain, which are then followed throughout the organism; (*g*) observation of certain metabolic anomalies and diseases, such as cystinuria; (*h*) observation of the metabolic processes of yeasts, bacteria, and other simple organisms, which has given valuable information on amino-acid metabolism; (*i*) paper chromatography and utilization by microorganisms are frequently used for the isolation and exact quantitative determination of amino acids.

Amino acids → Deamination → Non-N residue → Carbohydrate; Fat
Deamination → N residue → Transamination; Urea
Amino acids → Protein synthesis → Liver protein → Plasma protein → Tissue protein
Protein synthesis → Tissue protein
Liver protein → Hemoglobin

Temporary storage in the tissues. Amino acids are rapidly taken up from the blood by the tissues—mainly by the liver, where they are rapidly deaminized, the NH_2 group being converted into urea. In hepatectomized dogs, amino acids are not metabolized.

Protein synthesis. In rats fed on amino acids as the only source of nitrogen, their growth shows that the structural proteins of the tissues are synthesized from amino acids. In some cases this synthesis takes place at a very rapid rate; *e.g.*, after extirpation of 70 per cent of the liver in rats, the liver tissue is almost completely regenerated in 9 to 12 days. Another demonstration of the rate of protein synthesis has been obtained by administrating amino acids labeled with deuterium to rats. In 3 days, 10 per cent of the protein in the liver and 2.5 per cent of that in the muscles was found to be of recent formation.[1]

Certain anterior hypophyseal extracts provoke giantism and therefore an increase in body protein formation, similar to that observed in some cases of hyperfunction of the anterior hypophysis (giantism, acromegaly; see Chap. 52, The Hypophysis). Following the injection of these extracts, nonprotein nitrogen and amino acids in plasma decrease, as if the latter were fixed by the tissues at a higher rate than the normal.

The liver is the main site of production of plasma proteins. This must proceed at a rapid rate, because patients with kidney disease may lose 10 to 20 gm. of serum albumin daily for many months, without a decrease in plasma-protein concentration. Half the plasma proteins can be removed from the blood by plasmapheresis,[2] and the effects of different factors on their regeneration can thus be studied. Plasma proteins are rapidly regenerated and the normal concentration can be restored in 2 to 7 days. The administration of blood plasma, casein or plasma hydrolysate, or mixtures of amino acids, by mouth or intravenously, increases the rate of plasma-protein regeneration. Normal regeneration of plasma proteins is dependent on the diet. If an insufficient amount of protein is given there is hypoproteinemia, which, if sufficiently pronounced, causes generalized edema. Severe hepatic disturbances, caused experimentally or by disease, retard the formation and regenera-

[1] Ussing, H. H., *Nature*, **142**, 399, 1938.

[2] Blood is drawn and centrifuged, the plasma is discarded, and the erythrocytes are then suspended in saline and reinjected. This is repeated several times.

tion of plasma proteins. Regeneration of hemoglobin has priority over regeneration of plasma proteins.

Amino-acid synthesis. At one time amino-acid catabolism alone was studied, but later amino-acid synthesis was well demonstrated[1] for the nonessential amino acids; arginin is also synthesized at a slow rate. Synthesis of glycine is demonstrated by the following facts:

1. Milk proteins contain 0.1 to 0.3 per cent glycine; the proteins of sucklings contain 2.5 per cent glycine;
2. If benzoic acid is given to an animal it combines with glycine and is eliminated in the urine as hippuric acid:

$$\underset{\text{Benzoic acid}}{C_6H_5\cdot COOH} + \underset{\text{Glycine}}{CH_2NH_2\cdot COOH} \rightarrow \underset{\text{Hippuric acid}}{C_6H_5CONH\cdot CH_2\cdot COOH}$$
After a sufficiently long period of treatment more glycine will have been excreted than that contained in the whole organism at the beginning of the experiment plus that ingested while the experiment lasted.

Synthesis of glutamic, aspartic, and other amino acids has also been demonstrated. The formation of alanine has been observed in a surviving liver perfused with fluids containing ketone derivatives, ammonium salts, ammonium pyruvate, or ammonium lactate (Embden).

Deamination and transamination. The greater part of amino acids absorbed undergo deamination. The NH_2 group is split off and converted into urea; a small amount can be used in the formation of other amino acids. The deaminated residue is an α-ketoacid. It constitutes 90 to 95 per cent of the total mass and energy in the original amino acid.

Deamination can be produced by reduction, hydrolysis, or oxidation. In the organism it is mostly performed by oxidation, as follows:[2]

$$R\cdot\underset{|}{\overset{NH_2}{CH}}\cdot COOH + O \rightarrow R\cdot\overset{O}{\overset{\|}{C}}\cdot COOH + NH_3$$
Surviving tissue slices of liver or kidney also deaminize amino acids, but other tissues do not. In the dog the liver is the only important site of deamination and urea formation; neither of these processes occurs after hepatectomy in this species (Mann *et al.*).

Transamination consists in the transfer of NH_2 from an amino acid to another chemical compound, *e.g.*, a ketoacid, with the formation of another amino acid.[1] The enzymes that catalyze these reactions are known as transaminases, and pyridoxal phosphate acts as coenzyme. Schoenheimer and his associates[2] have shown that these processes are constantly taking place in the organism. A large proportion of absorbed N is incorporated into the tissues and there is a continuous dynamic exchange of nitrogen in the tissues. The idea that there are two different protein metabolisms—an exogenous protein metabolism, in which ingested protein is concerned, independent of the endogenous protein metabolism of tissue protein—can no longer be accepted. Protein is continuously being formed and decomposed in the cells. Moreover, nitrogen is transferred from one amino acid to another; thus, if leucine or glycine labeled with N^{15} is given, the isotope will be found in glutamic and aspartic acids, and in small amounts in valine but not in lysine.

Administration of N^{15} in ammonium citrate has shown that N^{15} is also transferred from this substance to amino acids. There is also proof of the formation and disintegration of amino-acid chains. Glutamic acid is the most active of the amino acids in this process.

Fate of the deaminized residue. After deamination the ketoacid residue is finally oxidized into CO_2 and water. In animals treated with phlorhizin it has been possible to demonstrate that this residue follows one of three paths. The so-called "glycogenic" amino acids form extra glucose and are excreted in the urine. They all have two to five carbon atoms (with the exception of arginine, which has six), and with the exception of lysine, they all have a straight chain; only one (proline) is a cyclical amino acid. The following are glycogenic amino acids: glycine; alanine; serine; threonine; cystine; aspartic, glutamic, and hydroxyglutamic acids; arginine (only three of its C atoms);

valine (only three of its C atoms); ornithine; and proline.

Ketogenic amino acids form acetoacetic acid. The following belong to this group: leucine, isoleucine, tyrosine, and phenylalanine.

Tryptophane, histidine, methionine, and lysine are neither glycogenic nor ketogenic.

THE END PRODUCTS OF PROTEIN CATABOLISM

Urinary excretion. The end products of protein catabolism are excreted in the urine. In mammals and other ureothelic animals, urea is the main end product; in birds and reptiles it is uric acid, and they are known as uricothelic animals.

The amount of total nitrogen, urea, and total sulfur excreted is in direct proportion to the amount of protein in the diet. The amount of urine excreted is in direct proportion to the amount of nitrogenous substances excreted. Folin supposed that these substances were the end products of ingested protein. This theory can no longer be accepted, because at least one-half of the nitrogen absorbed with food passes into the tissues and is not catabolized immediately. Urea excreted by fasting or fed animals is not formed exclusively from ingested amino acids; part, at least, derives from tissue proteins.

Protein seems to be actively catabolized. Thus an amount of N equivalent to 50 per cent of that which has been ingested in a meal is excreted by the dog in 4 to 5 hr.; by 12 to 16 hr. an amount equivalent to all the N ingested has been eliminated.

ingested. The normal range of urea concentration in blood is from 18 to 35 mg. per 100 cc. (equivalent to 8 to 15 mg. N). A concentration of 50 mg. per cent is definitely abnormal. An increase in blood urea is observed when it is not normally eliminated by the kidney, when there is insufficient elimination of water, or when it is formed in excess. The highest concentration that urea can reach in human urine is 55 gm. per liter; therefore if water is excreted in very low quantities, urea will be retained in the body.

Formation of urea by the liver has been demonstrated in many ways: (*a*) the liver has been perfused with blood to which ammonium salts or amino acids have been added; (*b*) urea is formed by tissue slices if amino acids or sodium salts are added; (*c*) deamination of amino acids and urea formation cease completely after hepatectomy in dogs:[1] (*d*) in patients with severe forms of hepatic disease, in which there is extensive destruction of liver cells, urea excretion diminishes to a minimum, and apparently little or no urea is formed.

The principal mechanism of urea formation seems to be that discovered by Krebs and Heinseleit[2] in which arginine is the precursor of urea. The NH_2 groups that have been split off from amino acids are converted into urea in three steps: (*a*) ornithine combines with ammonia and forms citrulline and water; (*b*) one molecule of citrulline combines with one molecule of ammonia and forms arginine and water; (*c*) arginine is hydrolyzed by arginase into ornithine and urea.

$$\underset{\text{Ornithine}}{COOH{\cdot}CHNH_2{\cdot}CH_2{\cdot}CH_2{\cdot}CHNH_2} + NH_3 + CO_2 \rightarrow \underset{\text{Citrulline}}{COOH{\cdot}CHNH_2{\cdot}CH_2{\cdot}CH_2{\cdot}CHNH{\cdot}CONH_2}$$

$$\downarrow + NH_3 \text{ from aspartic acid}$$

$$\underset{\text{Urea}}{CO(NH_2)_2} \leftarrow H_2O + \underset{\text{Arginase}}{} \underset{\text{Arginine}}{COOH{\cdot}CHNH_2{\cdot}CH_2{\cdot}CH_2{\cdot}CHNH{\cdot}C(NH)NH_2} \quad (\text{Ornithine} \uparrow)$$

Urea. A subject on a mixed diet excretes from 9 to 13 gm. of nitrogen daily. Most of this N is in the form of urea. If the subject is fed a mixed diet, 87 per cent of urinary N is in the form of urea; 95 per cent if a high-protein diet, and 60 per cent if a low-protein diet is ingested. Subjects on a mixed diet excrete 20 to 30 gm. of urea daily.

Urea is formed from the NH_2 group split off by deamination from amino acids; it is also formed from ammonium salts when these are

The process is not as simple as this; seven stages, with the intervention of several enzymes, are already known.[3] Aspartic acid is the NH_3 donor for the conversion of citrulline to arginine; other amino acids

[1] BOLLMAN, G. L., F. C. MANN, and T. B. MAGATH, *Am. J. Physiol.*, **69**, 371, 1924; *Ergebn. d. Physiol.*, **23**, 212, 1924.

[3] RATHNER, S., and S. GRISOLIA, Urea Formation A Symposium on Phosphorus Metabolism," Johns Hopkins Press, Baltimore, 1951.

can transfer it to aspartic acid by transamination. Carbamil glutamate gives CO_2 and NH_3 for the conversion of ornithine into citrulline. ATP (adenosine-triphosphate) takes part in all these reactions.

Ammonia. A subject on a mixed diet excretes in the urine from 0.4 to 1 gm. ammonia (2 to 5 per cent of total urinary N) every 24 hr.[1] The amount depends on the acid-base equilibrium of the organism. Thus it increases (*a*) if acids, such as HCl, which are not metabolized, are ingested; (*b*) if acids are formed in the organism, as when a protein diet is given, in acidosis, muscular exercise, pregnancy, or fever; (*c*) if there is diabetic acidosis. In this last case, there is a very great increase because β-hydroxybutyric and acetoacetic acids are excreted as ammonium salts. Urinary ammonia is diminished by (*a*) ingestion of alkali; (*b*) a vegetarian diet, which has more basic than acid end products.

In shed blood small quantities of free ammonia are found, but it is doubtful if there is any in circulating blood. Immediately after extraction 0.1 mg. per cent (Parnas and Heller) or 0.5 mg. per cent (Krebs) has been reported; if the blood is collected in an atmosphere of CO_2, only 0.004 mg. per cent is found (Conway).

Nash and Benedict[2] demonstrated that ammonia is formed in the kidney, and that there is more ammonia in the blood of the renal vein than in renal arterial blood. Renal production of ammonia prevents the loss of base in the urine; sodium and potassium salts are converted into ammonium salts in the kidney, the acid is thus eliminated, and the base is retained in the organism. Ammonia is formed from glutamine (the amide of glutamic acid) and not from urea, which is eliminated as such.[3]

$$\underset{\text{Glutamine}}{COOH{\cdot}CHNH_2{\cdot}CH_2{\cdot}CH_2{\cdot}CONH_2} + H_2O \rightleftarrows \underset{\text{Glutamic acid}}{COOH{\cdot}CHNH_2{\cdot}CH_2{\cdot}CH_2{\cdot}COOH} + NH_3$$
If ammonia is given to an animal it is converted into urea (mammals) or into uric acid (birds). In man and other mammals, when ammonium chloride is given, NH_4 is converted into urea and excreted; Cl^- is retained in the body, where it combines with fixed base (bicarbonate) and causes a decrease in the alkali reserve and acidosis.

Hippuric acid. There is only a small amount of this acid in human urine (0.7 to 1 gm. in 24 hr., *i.e.*, 3 to 5 per cent of total urinary N). It increases in subjects on a vegetarian diet (2 gm. or more). It is found in large quantities in the urine of herbivorous animals, which excrete from 50 to 150 gm. daily. It is formed by the combination of glycine and benzoic acid, a process that takes place in the kidney in some species (Bunge and Schmiedeberg), but mainly in the liver in most animals. Formation of hippuric acid after ingestion of benzoate is used as a test of hepatic function in man (Quick).

Creatine and creatinine. Creatine is methylguanidinacetic acid. Creatinine (methylglycocyamidine) is the anhydride of creatine.

$$\underset{\text{Guanidine}}{NH{=}C(NH_2)NH_2} \qquad \underset{\text{Creatine}}{NH{=}C(NH_2){-}N(CH_3){-}CH_2{-}COOH}$$

$$\underset{\text{Creatinine}}{NH{=}C{-}N(CH_3){-}CH_2{-}CO \text{ (ring closed through NH between C and CO)}}$$
Creatine is a constituent of the tissues and creatinine is excreted in the urine. There is 90 to 120 gm. of creatine in the human body; 98 per cent of this is in the muscles, 1.5 per cent in nerve tissue, and the rest in the testicle and other tissues. Muscle contains 350 to 400 mg. of creatine per 100 gm.; 80 per cent of this is in the form of phosphocreatine, a substance of great importance in the energetics of muscular contraction. Blood really contains very little creatine, but the methods currently used for its determination give artificially high results. Creatine is seldom found in urine.

There is very little creatinine in the tissues, but it is regularly found in urine. It is an end product of metabolism that the organism cannot utilize. Thus if creatinine labeled with N^{15} is administered to an animal, all of it will be found in the urine. If, on the other hand, creatine labeled with N^{15} is administered it is not found in the urine, unless very large amounts are given. It is retained in the tissues and is later excreted

[1] If urine is left standing at room temperature without an antiseptic, ammonia is formed from urea by bacterial action.

[2] Nash, T. P., *J. Biol. Chem.*, **48,** 663, 1921; **51,** 183, 1922; Nash, T. P., and S. R. Benedict, *J. Biol. Chem.*, **69,** 381, 1926; **82,** 673, 1929.

[3] Van Slyke, D. D., R. A. Phillips, P. B. Hamilton, R. M. Archibald, P. M. Futcher, and A. Hiller, *J. Biol. Chem.*, **150,** 481, 1943.

as creatinine. The administration of protein or amino acids increases formation and excretion of creatine and creatinine in the rat. This fact has led Beard to suppose that all the amino acids can produce creatine, but Rose believes this is due to stimulation of creatine metabolism and that amino acids are not necessarily creatine precursors.

More recent studies[1] have led to the conclusion that creatine is formed by the interaction of three substances: glycine, arginine, and methionine. Glycine is absorbed with the food or formed in the course of metabolism. Arginine is the source of the guanidine group. Methionine, choline, or other substances act as methyl donors. The process is as follows:

$$\underset{\text{Arginine}}{R\cdot C(NH_2)=NH} + \underset{\text{Glycine}}{CH_2(NH_2)-COOH} \rightarrow \underset{\text{Guanidinacetic acid}}{NH=C(NH_2)-NH-CH_2-COOH} + \underset{\text{from Methionine}}{CH_3} \rightarrow \underset{\text{Creatine}}{NH=C(NH_2)-N(CH_3)-CH_2-COOH}$$

Creatinine is, with the exception of urea, the most abundant of the nitrogenous substances in urine. An adult man excretes 1 to 1.5 gm. daily (3 to 6 per cent of total urinary N). Folin considered creatinine excretion to be constant, and established a "creatinine coefficient," *i.e.*, the amount excreted per kilogram per hour; normally he found this to be 20 to 26 in man, 14 to 22 in women, and 30 in athletes. Apparently there is some relation between creatinine excretion and muscular development. Creatinine arises from creatine (phosphocreatine) in muscle, which is maintained at a constant level and is metabolized at a constant rate, even during fasting. The conversion of phosphocreatine into creatinine, with liberation of phosphorus, has been demonstrated recently. Probably this is the path usually followed in the formation of creatinine by animal tissues.

The only significant precursors of creatinine are guanidinacetic acid and glycine. Guanidinacetic acid is methylated and creatine formed only in liver tissue. In the disease known as "pseudo-hypertrophic progressive muscular dystrophia" usually there is creatinuria, which increases if glycine is given; in some cases glycine administration has been followed by improvement of the condition.[2]

Creatine is not a normal constituent of adult human urine. Creatinuria may be observed in the following circumstances: (*a*) commonly in children; (*b*) sometimes in women, regularly during pregnancy, puerperium (even if hysterectomy has been performed), and lactation; (*c*) in complete fasting, carbohydrate fasting, and diabetes; (*d*) in thyrotoxicosis and in fever; (*e*) in poliomyelitis, muscular dystrophia, myasthenia, and certain mental diseases. According to Beard, creatinuria is related to disturbances in phosphorus metabolism.

Blood serum has small amounts of creatine (0.42 mg. per cent) and creatinine (1.07 mg. per cent). An increase of these substances in the serum is a sign of nitrogen retention in renal insufficiency.

Creatinine excretion increases in inanition, fever, thyrotoxicosis, and diabetes. Creatinine in the blood plasma is filtered through the renal glomerulus, and in man a small amount is added in the renal tubes. In renal diseases with disturbance of nitrogen excretion, blood creatinine increases because of faulty elimination. Creatinine concentration in blood can therefore be taken as a sign of the state of nonprotein nitrogen excretion.

$$\text{Creatine} + PO_4^{-3} \rightarrow \underset{\text{Phosphocreatine}}{HN=C(NHPO(OH)_2)-N(CH_3)-CH_2\cdot COOH} \rightleftarrows \underset{\text{Creatinine}}{HN=C\langle NH-CO-CH_2-N(CH_3)\rangle}$$

The metabolism of sulfur. Almost all the proteins contain sulfur combined in cystine and methionine. Sulfur is particularly abundant in the protein of the hair and nails. It is also found in some glucoproteins, *e.g.*, in mucoitinsulphuric acid in mucin and in chondroitinsulfuric acid in

[1] Bloch, K., and R. Schoenheimer, *J. Biol. Chem.*, **138**, 155, 1941.

[2] Brand, E., *et al.*, *Am. J. Physiol.*, **90**, 296, 1929.

cartilage. Cystine gives rise to cysteine, glutathione (a tripeptide formed by glutamic acid, cysteine, and glycine), and taurine, which combines with cholalic acid to form the taurocholic acid in bile.

Cystine and methionine are completely oxidized into sulfates by the tissues. Methionine is one of the essential amino acids that must be included in the diet, although man needs relatively less than other species. In some animals

$$CH_3-S-(CH_2)_2-CHNH_2-COOH$$
Methionine

$$HOOC-CHNH_2-CH_2-S-S-CH_2-CHNH_2-COOH$$
Cystine

$$SH-CH_2-CHNH_2-COOH$$
Cysteine

$$SO_2OH-CH_2-CH_2NH_2$$
Taurine

it increases the retention of nitrogen in the organism, but not in man. It is converted into cystine by the tissues. Methionine acts as a methyl donor[1] in the formation of choline, creatine, and other substances. Methionine in the diet protects the liver from necrosis and cirrhosis produced by low-protein–high-fat diets.

Sulfur is also a component of vitamin B_1 (thiamine) and some of the hormones (insulin, anterior hypophyseal hormones).

Sulfur is found in three forms in the urine: (*a*) inorganic sulfur, (*b*) ethereal sulfate; (*c*) organic, or neutral, sulfur.

In the course of metabolism the greater part of cystine and methionine is oxidized, and sulfates of K, Na, Ca, and NH_3 are formed; this makes up 80 to 90 per cent of total urinary sulfur.

Ethereal sulfates (5 to 8 per cent of total urinary sulfur) are compounds of sulfuric acid and phenol or cresol derived from phenylalanine or tyrosine, and indoxyl or skatoxyl derived from tryptophane. These substances are formed by the action of bacteria in the intestine; part of these bacterial products are absorbed and combined with sulfuric acid. Sulfoconjugation of phenols is performed in many tissues, *e.g.*, the intestine, liver, etc., but it is still actively carried out even in hepatectomized animals. Sulfur compounds of phenol are less toxic than phenol, and for this reason sulfoconjugation is considered a disintoxicating or protective mechanism. The elimination of ethereal sulfates in urine (urinary indican) indicates the rate of intestinal putrefaction. Intestinal antiseptics diminish or even suppress urinary indican.

Neutral sulfur (4 to 6 per cent of total urinary sulfur) consists of cystine, urochrome sulfocyanide, and other organic compounds of sulfur.

Inorganic urinary sulfur is, together with urea, an index of protein catabolism. The excretion of sulfate and of urea varies simultaneously and in the same direction, except for a few transitory discrepancies.

Certain individuals excrete cystine in the urine. This rare metabolic anomaly is called cystinuria. Not only is there a disturbance in cystine metabolism, but other amino acids (lysine, arginine, ornithine) also increase in the blood and urine. Cystine is almost insoluble in water; therefore it crystallizes in the urine (urinary "sand") or forms stones in the urinary tract. Crystals of cystine may also be found in the bone marrow and other tissues.

CATABOLISM OF CYCLIC AMINO ACIDS

Phenylalanine and tyrosine. These amino acids are constituents of a large number of proteins. Phenylalanine is one of the essential amino acids that must be included in the diet. The administration of phenylalanine labeled with deuterium shows that it is converted into tyrosine, but tyrosine is not converted into phenylalanine. Oxidative deamination of phenylalanine and tyrosine gives *p*-hydroxyphenylpyruvic acid; this process has been obtained *in vitro* with slices of surviving tissues. A single case has been reported by Medes (1932) in which a patient eliminated *p*-hydroxyphenylpyruvic acid in the urine spontaneously or following the administration of phenylalanine or tyrosine. The disturbance has been called "tyrosinosis." In normal subjects the benzene ring of these amino acids is broken, and acetoacetic

[1] Du Vigneaud, V., "Interrelationships between Choline and Other Methylated Compounds, *Biol. Symposia*, 5, 234, 1941.

acid is formed; this has been demonstrated by experiments in phlorhizinized dogs.

In certain subjects alkaptone (homogentisic or 2.5-dihydroxyphenylacetic acid) is eliminated in the urine, which becomes black when left standing in contact with air or when alkali is added. The urine reduces Fehling's and Benedict's reagent and gives a violet color with ferric chloride. Alkaptonuria increases after the administration of phenylalanine or tyrosine. Deposition of alkaptone in tissues (sclerotic, cartilage) produces a gray or brown pigment (ochronosis). This metabolic anomaly is inherited as a mendelian recessive character.
$CH_2{\cdot}CH{\cdot}NH_2COOH$ Phenylalanine; OH / $CH_2{\cdot}CH{\cdot}NH_2COOH$ Tyrosine; OH / $CH_2CO{\cdot}COOH$ *p*-Hydroxyphenylpyruvic acid; HO, OH / $CH_2{\cdot}COOH$ Homogentisic acid

Phenylalanine is the precursor of tyrosine, of adrenaline produced in the adrenal medulla and of diiodotyrosine and thyroxine produced by the thyroid. Tyrosine and adrenaline can form black or red pigments.

Phenylketonuria. Phenylpyruvic acid has been found in the urine of mentally deficient patients (0.5 per cent of the inmates in an asylum for mental deficients) who suffered from a mental condition which has been called phenylpyruvic imbecility (Folling, 1934). Phenylpyruvic acid is formed in the kidney from phenylalanine which is not converted into tyrosine.

Tryptophane. This is one of the essential amino acids. It can give rise to a certain amount of the pellagra-preventing (P-P) vitamin. Administration of tryptophane causes the formation of kinurenic acid in some species, but not in man. Intestinal bacteria form indole and skatole from tryptophane, which are partially reabsorbed. Indole is converted into indoxyl by the tissues, mainly in the liver, and then into potassium indoxylsulfate (urinary indican), which is found in the blood and tissue fluids and is eliminated by the kidney. It is an index of intestinal putrefaction.

Indole nucleus; —OH Indoxyl; —O—S(=O)(=O)—OK Urinary indican
If there is a disturbance in renal excretion its concentration in blood will be found to be persistently high, and it will be eliminated at a slow rate after injection. Retention of indican usually occurs simultaneously with that of nonprotein nitrogenous substances.[1]

Pyrollic amino acids. Proline and oxyproline are completely disintegrated in the organism following the path of the tricarboxylic cycle. Three of the carbon atoms can be utilized for the formation of glucose.

Histidine. This is imidazol-α-aminopropionic acid, which is completely oxidized in the body. A small amount may be found in normal urine, and larger quantities in the urine of pregnant women. In shock, in allergic reactions, and by the action of bacteria, histidine can give rise to histamine (β-imidazolethylamine). This substance has a potent effect: it can produce shock. It contracts smooth muscles, dilates the capillaries, and increases the passage of fluid from the blood to the tissues. In all tissues, except the lung, an enzyme that destroys histamine has been found; it is called histaminase. Histidine is considered a precursor of purine bases in the body.

ENDOCRINE REGULATION OF PROTEIN METABOLISM

Certain hormones, in adequate amounts, are indispensable for normal growth and therefore for the formation of tissue proteins. In thyroid and hypophyseal insufficiencies, growth is retarded and less nitrogen is retained for protein formation than in normal subjects. Protein catabolism is also retarded and in complete fasting or in protein fasting less nitrogen is eliminated in the urine. Anterior hypophyseal or thyroid treatment restores the normal condition in the respective insufficiencies.

Testicular hormones are also important in the stimulation of protein anabolism. The muscular development of castrates is less than that of normal individuals, and in many cases testosterone causes retention of nitrogen, even in normal subjects.

[1] An examination of substances that give rise to indoxyl or indoleacetic acid has been made by Stoppani (*J. Biol. Chem.*, **157**, 1, 1945).

In cases of hyperfunction of the anterior hypophysis (giantism, acromegaly) there is an increase in the development of the body, due to an increase in protein anabolism (see Chap. 52, The Hypophysis).

Giantism can be produced in rats and dogs by the administration of anterior hypophyseal extract. After each injection, nonprotein nitrogen in the blood and urinary excretion of nitrogen diminish. This effect is apparently due to the taking up of nitrogen by the tissues for the synthesis of protein.

In the first stages of certain cases of corticoadrenal hyperfunction, there is a precocious and abnormally great development of the muscles, even in women and children.

Small doses of thyroid can transitorily improve growth in some cases, but hyperthyroidism, especially in severe cases, causes an increase in protein catabolism, the minimum protein requirement rises, and creatinuria may be observed. The adrenals play an important part in the increase in protein catabolism observed in diabetes, anoxia, and other conditions. Some of the anterior hypophyseal and corticoadrenal hormones increase the formation of glucose from protein when the subject is fasting or when there is already extra glucose formation (diabetes). Adrenalectomy or hypophysectomy, on the contrary, diminishes nitrogen excretion, hyperglycemia and glycosuria in diabetic animals.

THE METABOLISM OF NUCLEOPROTEINS

Nucleoproteins are conjugated proteins; hydrolysis splits them into a nuclein and a protein. Nucleins are formed by a nucleic acid and a basic protein (histone or protamine). The best known of the nucleic acids are thymus nucleic acid and yeast nucleic acid. At one time these were considered as typical of animal and plant organisms respectively, but later thymus nucleic acid was found in plants, and yeast (or ribonucleic) acid was found in animals.

Nucleic acids were given the name because they were first isolated from nucleoproteins obtained from cell nuclei.[1] Later, nucleic acids were found in the cytoplasm.

The nucleic acid in chromatin has desoxyribose in its molecule; it is known as "desoxyribonucleic" or "chromonucleic" acid. In the cytoplasm and nucleoli of animal cells there is nucleic acid with ribose in its molecule, known as "ribonucleic" or "plasmonucleic" acid.

Desoxyribonucleic acid gives a positive Feulgen test, *i.e.*, fuchsin bleached by sulfurous acid recovers its red color. The nucleus and chromosomes also give a positive Feulgen test. Chromatin owes to nucleic acid its affinity for basic stains. Nucleic acids can be identified in sections of tissue by their absorption spectra (Caspersson).

Nucleic acids are of considerable biologic importance. They form part of the specific protein of viruses and of chromosomes. The latter constitute the physical basis of heredity and play a leading part in cell division and in the metabolic and secretory activities of the cells. Nucleic acids are apparently of fundamental importance for the formation of the specific substances of the organism.

Table 52. Composition of Nucleic Acid

Constituents	*Thymus and nuclear chromatin; desoxyribonucleic acid*	*Yeast and cytoplasm; ribonucleic acid*
Phosphoric acid...	Phosphoric acid	Phosphoric acid
Sugar...........	Desoxyribose	*d*-Ribose
Purine bases......	Adenine and guanine	Adenine and guanine
Pyrimidine bases...	Cytosine and thymine	Cytosine and uracil

A nucleic acid unit is made up of four nucleotides. Each nucleotide is formed by (*a*) phosphoric acid; (*b*) a pentose; (*c*) a nitrogenous base (Table 52). Two of the nitrogenous groups are purine bases, adenine and guanine, and two are pyrimidine bases, thymine and cytosine. According to Levene, desoxyribonucleic acid (chromonucleic) or thymus nucleic acid is made up of the following four nucleotides:

Adenine-desoxyribose-phosphoric acid
= adenine-nucleotide or adenylic acid
Thymine-desoxyribose-phosphoric acid
= thymine-nucleotide
Cytosine-desoxyribose-phosphoric acid
= cytosine-nucleotide
Guanine-desoxyribose-phosphoric acid
= guanine-nucleotide or guanylic acid

[1] Nucleic acid was discovered by Miescher (1871) and purines by Kossel (1879–1881). The structure of purines was first described by Emil Fischer (1907) and the constitution of tetranucleotides by Levene (1909–1931).

Uracil takes the place of thymine in ribonucleic acid.

Most nucleic acids have a high molecular weight, therefore they must be made up of several of these units (tetranucleotides), or else they have a more complex structure. Hydrolysis splits up nucleic acid into its constituent nucleotides; phosphatase splits off the phosphoric acid of the nucleotide and leaves a residue (called a nucleoside) formed by the nitrogenous (purine or pyrimidine) base bound to the sugar. The nitrogenous base undergoes deamination while it is still bound to the pentose or after it has been separated. The following are some of the nucleosides:

Adeninepentose, or adenine-nucleoside, or adenosine.
Guaninepentose, or guanine-nucleoside, or guanosine.
Hypoxantinepentose, or hypoxantine-nucleoside, or inosine.

There are three mononucleotides in the tissues that do not form part of nucleic acids but are apparently part of the cell protoplasm. These are

1. Adenosinephosphoric acid, found in muscle. The pentose is *d*-ribose, and it can be united to two or three molecules of phosphoric acid (ADP and ATP). It is important in the chemistry and energetics of muscular contraction.
2. Inosinic acid, also found in muscle. It is formed by hypoxantine, *d*-ribose, and phosphoric acid.
3. Guanylic acid, found in glandular tissue (*e.g.*, the pancreas). It is formed by guanine, *d*-ribose, and phosphoric acid.

These and other similar organic compounds of phosphorus are of great physiologic importance. Thus in cell respiration two dinucleotides act as hydrogen carriers (acceptors and donors). One is diphosphonicotinic amide adenine, or coenzyme I; the other is triphosphonicotinic amide adenine, or coenzyme II.

Digestion and absorption. Pepsin hydrolyzes nucleoproteins into nuclein and protein. Trypsin goes one step further and separates the nucleic acids of nucleoproteins. Enzymes called "nucleases" in the intestinal mucosa and secretion disintegrate nucleic acid into its constituent nucleotides. Other enzymes in the intestinal mucosa, called "nucleotidases" and "nucleosidases," carry hydrolysis still further. Nucleotidases (which are phosphatases) split off phosphoric acid from nucleotides and convert them into nucleosides, which are divided into their respective purine or pyrimidine bases and sugars by nucleosidases. The intestinal mucosa absorbs nucleosides, purine or pyrimidine bases, pentoses, and phosphoric acid. Resynthesis of nucleic acid takes place in the body, but its mechanism is still unknown.

Nucleoprotein catabolism. The disintegration in the organism of the nucleosides absorbed and of nucleoproteins is carried out in a similar way to that just described.

The following diagram gives a summary of the processes of disintegration of nucleic acid:

Nucleic acid
Nuclease ↓

↓ *Nucleotidase* (phosphatase) ↓

Hypoxanthosine ←* Adenosine | Guanosine →* Xanthosine

↓ *Nucleosidase* (splits off sugar and base) ↓

Adenine | Guanine | Pyrimidine bases

↓ *Adenase* *Guanase* (deamination) ↓

→ Hypoxanthine → Xanthine | Urea + CO_2 + H_2O

Xanthinoxidase (oxidation)

Xanthine
↓ *Xanthinoxidase* (oxidation)
Uric acid
↓ *Uricase*
Allantoin

* Deamination.

Uric acid is a derivative of purine bases. Free purine bases, and even those combined in nucleosides, undergo deamination by specific enzymes; thus adenase converts adenine into hypoxanthine, and guanase converts guanine into xanthine. Hypoxanthine is oxidized into xanthine; the latter is oxidized into uric acid by xanthine-oxidase (xanthine dehydrase).

Autolysis of spleen and liver pulp (both of which contain much nuclear substance) in the presence of blood gives rise to xanthine. If air is

Table 53. Enzymes Acting on Nucleic Acids and Their Derivatives

Enzyme	*Substrate*	*Effect*	*Distribution*
Ribonuclease	Ribonucleic acid	Depolymerization	Pancreas, liver, lungs, leukocytes
Desoxyribonuclease	Desoxyribonucleic acid	Depolymerization	Pancreas, intestinal mucosa, etc.
Nucleotidases (phosphatidases)	Nucleotides	Dephosphorylation	Intestine, liver, etc.
Nucleosidases	Nucleosides	Hydrolysis or phosphorolysis*	Liver, spleen, heart, etc.
Deaminases	Adenine, guanine, adenylic and guanylic acids, adenosine, guanosine, etc.	Hydrolysis at the amine with production of ammonia	Several tissues
Xantinoxidase	Hypoxantine, xantine	Oxidation to uric acid	Liver
Uricase	Uric acid	Oxidation to allantoin	Liver

Source: SUMNER, J. B., and G. F. SOMERS, "Chemistry and Methods of Enzymes," Academic Press, Inc., New York, 1947.

*Phosphorolysis of nucleotides gives ribose-1-phosphate and the nitrogenous base. The process is reversible and therefore also acts as a mechanism of synthesis.

made to bubble through the mass, xanthine is oxidized into uric acid (Hosbaczewski, 1891).

In man and the anthropoids the end product of purine metabolism is uric acid, which is excreted in the urine. In other mammals the greater part of uric acid formed is oxidized by an enzyme, called uricase, into allantoin, which is eliminated in the urine. Oxidation of uric acid can be expressed by the uricolytic index:

$$\frac{\text{Allantoin N} \times 100}{\text{Allantoin N} + \text{Uric acid N}}$$

This index equals 0 in the chimpanzee and 2 in man; in other mammals it varies from 89 to 98. The Dalmatian coach hound has a low index (32); uric acid is the main end product of purine metabolism in this species.

In the dog, uric acid formed in the body or injected is oxidized by uricase in the liver and eliminated as allantoin in the urine. In hepatectomized dogs the uric-acid concentration in blood rises, and urate appears in the urine. If uric acid is then injected, it is no longer excreted as allantoin, but as uric acid.[1] In man there is no uricase in the liver; therefore uric acid formed in the body is eliminated as such. If it is injected, 70 to 100 per cent is eliminated in the urine; the rest is excreted by the intestine or destroyed by bacteria. Uric acid filters through the renal glomeruli and is in part reabsorbed in the renal tubes. The mechanism regulating renal excretion of uric acid is not well known.

The steps in the metabolism of pyrimidine bases are still unknown. The end products of their oxidation are urea, CO_2, and water.

Purine synthesis. Synthesis of purine and nucleoproteins in the organism is proved by many facts: (*a*) purine bases increase in the hen's egg in the process of incubation; (*b*) young mammals are fed almost exclusively on milk, which contains little or no purine, but at that age nuclei are being formed in large quantities; (*c*) a Dalmatian coach hound excreted 100 gm. uric acid in the course of 1 year, during which period it was fed on a diet free from purine (Benedict); (*d*) men who were fed diets without purine for long periods kept in good health and continued to excrete uric acid during the whole period; (*e*) administration of NH_3 labeled with N^{15} is followed by the excretion of purine containing N^{15}; (*f*) glycine is a precursor of purines and of uric acid.

Uricothelic animals. In mammals and amphibians the greater part of nitrogen in protein catabolism is excreted as urea. Uric acid in these species arises exclusively in nucleoprotein and purine catabolism. These animals are known as ureothelic.

In birds and reptiles the principal end product of protein metabolism is uric acid, which arises not only from nucleoprotein, but also from amino-acid catabolism. These animals are called uricothelic. In the goose 60 to 70 per cent of total urinary N is in the form of uric acid, 3 to 5 per cent in urea, and

[1] BOLLMAN, J. L., and F. C. MANN, *Am. J. Physiol.*, **104**, 242, 1933.

10 to 18 per cent in ammonia. Uric acid is formed mainly in the liver. After hepatectomy (Minkowski) uric acid excretion diminishes considerably and there is a marked increase in ammonium lactate. Perfusion of an isolated liver with ammonium lactate gives rise to the formation of uric acid. After the administration of NH_3 labeled with N^{15}, the isotope is found in uric acid.

Excretion of uric acid. Urinary uric acid is said to be endogenous (from nucleoproteins in the tissues) and exogenous (from nucleoproteins in food). Total fasting does not suppress completely the excretion of uric acid, but the amount eliminated increases when there is purine or nucleoprotein in the diet. A normal man on a mixed diet excretes from 0.5 to 1 gm. of uric acid daily, but this figure increases to 1.5 or 2 gm. daily when the diet contains many purine precursors. Purine base is also found in the urine, but only in small quantities (between 15 and 50 mg. daily).

The greater part, perhaps all, of the uric acid eliminated arises from purine or from substances that contain purine. Foodstuffs that contain much nuclear substance (thymus, pancreas, liver, kidney, brain, and meat extract; in a lesser degree, meat, peas, beans, and spinach) increase uric acid excretion. Milk, cheese, cream, and starchy foods contain little or no purine.

A high-protein diet increases the excretion of uric acid in proportion to the caloric value of the diet. Urinary uric acid increases after violent exercise and in fever that is accompanied by a higher rate of protein catabolism. Probably in these cases uric acid arises from adenylic acid in muscle. There is also an increase in uric-acid excretion when there is an excessively active nuclear metabolism, *e.g.*, in leukemia (up to 12 gm. daily), polycythemia, reticulocytosis provoked by liver extracts used in the treatment of pernicious anemia, etc.

Certain beverages contain methylpurines, such as caffeine (in coffee and maté), theophylline (in tea), theobromine (in cocoa, and a little in maté). These are excreted as methylpurines, not as uric acid. Uric-acid excretion is increased by methylpurines only when they act as diuretics, and it is not then a specific effect, since all diuretics increase uric-acid excretion (Thannhauser).

To diminish uric-acid excretion the diet should contain little or no purine and little protein. It should be of low caloric value and should consist mainly of fat and carbohydrate.

Uricemia. There is 2 to 5 mg. per 100 cc. of uric acid in human blood, which is a much higher concentration than that found in the dog. It increases if there is excess production or if it is retained owing to deficient elimination.

The concentration of uric acid in blood is higher in adult men than in women, and gout occurs more frequently in men than in women. When the uric-acid concentration in the blood rises above 5 mg. per cent, the condition is called hyperuricemia. It is observed in (*a*) gout; (*b*) leukemia and polycythemia; (*c*) pneumonia; (*d*) nephritis and the so-called "toxemia of pregnancy." In chronic nephritis blood uric acid rises together with nonprotein nitrogen. Some workers maintain uric acid is one of the first substances to increase in the blood when there is nitrogen retention due to kidney disease.

Gout. In this disease there are (*a*) hyperuricemia, *i.e.*, abnormally high uric-acid concentration in the blood (from 6 to 10 mg. per 100 cc.); (*b*) formation of deposits of sodium urate crystals known as "tophi" in the tissues, particularly in the cartilages of the joints; (*c*) repeated attacks of acute inflammation of the joints. The reason for the deposition of sodium urate crystals is not known. Blood plasma is not saturated with uric acid, and in other diseases (*e.g.*, leukemia, chronic nephritis) there is greater hyperuricemia than in gout without the formation of urate crystals. The uric-acid pool in the organism is increased in subjects with gout, a fact which has been revealed by means of injections of uric acid labeled with an isotope.

Hyperuricemia in gout is not due to excess formation of uric acid, as normal amounts are excreted. Sometimes uric-acid excretion diminishes just before an attack and increases at the beginning of the attack. It would seem that hyperuricemia is due to a selective retention of uric acid by the kidney. Uric-acid clearance at the same level of blood uric acid is below normal in patients with gout. Uric acid injected intravenously into patients with gout is eliminated at a slower rate than in normal subjects. Salicylates, atophan, and cinchophen increase uric-acid elimination in normal and gouty subjects and relieve pain during the attacks of gout.

CHAPTER 44

Water Metabolism

The properties of water. Water is quantitatively the main constituent of the body. It is also the universal medium in which all living processes take place; life is not possible without water. The importance of water in biology is due to its remarkable physical and chemical properties. It is the fluid that can dissolve the largest number of substances. Some of these undergo molecular dispersion, others form particles of larger size (micellae of colloidal dispersions), and others are dissociated into ions. Ionic dispersion (*i.e.*, electrolytic dissociation) is made possible by the great dielectric constant of water, which is greater than that of any other liquid. Water plays an essential part in the regulation of body temperature, owing to the following properties:

1. It has a high specific heat, which permits storage of a large amount of heat without a great increase in temperature.
2. It conducts heat, thus assuring its distribution and the establishment of a uniform temperature throughout the body. The circulation is an important factor in the distribution of heat.
3. Its great latent heat of vaporization (540 kg.-cal. is needed to evaporate 1 liter of water) plays a major part in the elimination of heat from the body.

The maximum density of water is at four degrees (centigrade) above its freezing point. This is the reason that ice floats instead of sinking. If the ice on the sea had sunk to the bottom, it would have gradually accumulated and prevented all marine life. Water has been used to establish certain standards, *e.g.*, it is taken as the unit of specific gravity; its freezing and boiling points are taken as 0° and 100° in the centigrade scale of temperature. Water has also a high surface tension. These outstanding properties, unequaled by those of any other fluid, give water not only an essential importance in biology but also great economic and social value.

The amount of water in the body. Concentration of water in the body diminishes throughout life. It is 90 per cent of the body weight in the embryo and 60 to 70 per cent in adults (73 per cent, discounting fat); it is even less in old age. The child not only has a higher concentration of water than the adult; its aqueous equilibrium is also less stable. In the adult, water intake and output are well regulated so as to maintain a constant concentration within narrow limits. When there is excess of water it is rapidly eliminated, and water is retained as soon as its concentration becomes insufficient (Adolph).

Water is found in greatest quantities in the muscles, and next in the skin. Ingested or injected water is taken up mainly by these tissues. In certain abnormal conditions large quantities of water are deposited in the subcutaneous tissue and in the serous cavities (edema).

The amount of water in 100 gm. of tissue is high in the blood, liver, muscles, and skin, and low in cartilage and bone (Table 54-A). It diminishes gradually with age.

Water balance. There are two sources of body water: (*a*) water ingested in food and beverages; (*b*) water formed by the oxidation of hydrogen in the course of metabolism.

The amount of water drunk varies from one individual to another, and from one day to another in the same individual. In temperate climates it varies between 850 and 2,500 ml. per day; on an average 1 ml. per kg.-cal. of heat output. It increases during work and when the temperature of the environment rises. In a hot climate, especially if manual labor or exercise is

performed, water intake can rise up to 2 liters/hr. and 10 or even 13 liters daily; in a hot desert an intake of 6 liters per day is quite usual. Most food contains 60 to 90 per cent water.

An important source of water is the oxidation of foodstuffs or substances stored in the body.

Table 54-A. Distribution of Water in the Tissues

	Weight, kg.	*Percentage of body weight*	*Water*	
			Percentage	*Total* liters*
Body........	70	....	66	46.0
Muscles.....	30	42	76	22.8
Skin........	12	18	72	8.5
Fat.........	13	18	30	3.8
Bones.......	11	16	22	2.4
Blood.......	5.6	8	76	4.2
Liver.......	1.5	2.2	70	1.0

* For a man weighing 70 kg.

Thus for every 100 gm. of fat burned 107 gm. of water is formed; and 55 gm. and 41 gm. for every 100 gm. of starch and protein respectively. This so-called "metabolic water" adds up to 300 or 350 cc. per day (Table 54-B).

Little or no water is absorbed in the stomach. Most of the water ingested is absorbed in the small intestine, and a smaller amount in the large intestine. The latter can absorb up to 80 cc. per hr.; this is utilized in therapeutics for the administration of saline solution by rectum, using the drop method. Isotonic saline solution is also absorbed when injected subcutaneously, intramuscularly, or into a serous cavity. Sodium chloride is rapidly absorbed from the intestine together with water. Other salts, such as magnesium sulfate, are not so easily absorbed; therefore, if they are in a high concentration water will diffuse into the lumen of the intestine and a cathartic effect will result.

Water is eliminated mainly by (*a*) the kidney (1,000 to 1,500 ml. per day); (*b*) the skin (450 to 1,050 ml. daily); (*c*) the lung and air passages (evaporation of 250 to 300 ml. daily); (*d*) the intestine (50 to 200 ml. daily in the feces). In the lactating female a large amount of water is eliminated by milk secretion. Occasionally water is lost in tears, nasal secretion, saliva, secretions of the genital tract, vomiting, or diarrhea.

The amount of water eliminated varies in different circumstances. Thus the volume of urine increases when more salts and nitrogen are eliminated and, generally speaking, when metabolism increases. The output of water is closely related to the intake; *e.g.*, urinary excretion may rise to 10 and even 40 liters per day

Table 54-B. Water Balance of Adult Man, with Moderate Activity at a Temperature of 18 to 20°C.

Intake		*Output*	
Source	*Volume, cc.*	*Route of elimination*	*Volume, cc.*
Beverages......	1,000	Kidney........	1,500
Food..........	1,200	Skin..........	600
Oxidations.....	300	Lung..........	300
		Feces..........	100
Total........	2,500	Total.......	2,500

(polyuria) if large quantities of water are taken (polydipsia). Excessive loss of water causes anhydremia (dehydration); this is seen in cases of digestive fistulas, repeated vomiting, profuse diarrhea, etc.; a typical example is dehydration in patients suffering from cholera.

Cutaneous evaporation of water in basal conditions is 30 to 40 gm. per hr. in a normal subject. This is known as "insensible perspiration" because the water evaporates as soon as it is excreted. When the temperature of the environment rises, sweat secretion increases. The amount of increase depends on the activity of the individual, the clothes worn, and the humidity of the atmosphere. In a hot, dry climate, when performing heavy labor, 5 to 10 kg. per day may be lost by sweating if water is not taken in order to compensate this loss.

Distribution of water. The water in the body is distributed in three separate compartments: (*a*) the blood plasma; (*b*) the tissue fluids—these two constitute the extracellular fluid—(*c*) the intracellular fluid (Fig. 206). There is a continuous exchange of fluid between these compartments; thus in 1 min. a volume of water equal to the water content of plasma enters and leaves the blood vessels.

The amount of water in blood plasma is only about 3 liters, but it is of great importance, because blood plasma is the means of communication between the external environment and the internal environment that surrounds

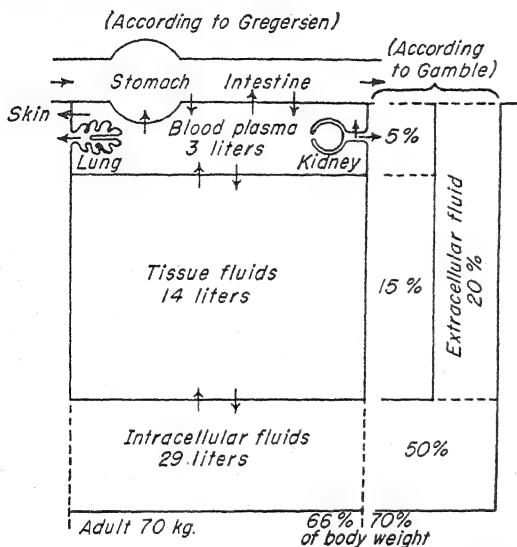
the cells. It circulates at great speed, and its composition is maintained rigorously constant. Its amount is 45 cc. (37 to 58 cc.) per kg. of body weight; therefore a subject weighing 70 kg. has 3,200 cc. of blood plasma, of which 3,000 is water and 200 protein.


Fig. 206. Diagram of distribution and circulation of water in the organism. (*After Gamble and Gregersen.*)

Extracellular fluid is the sum of blood plasma and tissue fluids. The mineral content of the fluid in these two compartments is similar, but it differs considerably from that of intracellular fluid (Fig. 207). The principal cation in the cells is potassium, and phosphate and protein are the principal anions. The principal cation of extracellular fluid is sodium, and the principal anions are chloride and bicarbonate. The main difference between blood plasma and tissue fluids is in the protein content, because the membrane of the capillaries is permeable to water and salts, but not to protein and other colloids. Proteins in blood plasma, especially serum albumin, exert an osmotic pressure greater than that of proteins in tissue fluids (Starling), but in spite of this the total osmotic pressure is the same in the three compartments, and there are accurate mechanisms that maintain its constancy. Tissue-fluid volume can be determined by several methods. In one method the total sodium or chloride content of the body is measured and then the content in blood plasma is subtracted. In this method it is supposed that sodium and chloride are evenly distributed in all extracellular fluids and that there is none in the cells. There is, however, no proof that NaCl is always in the same concentration in all tissue fluids as in plasma. Moreover, NaCl has been found in small quantities in several tissues.

The method most commonly used for measuring tissue fluids consists in the injection of a known quantity of a substance, such as sodium sulfocyanide (Crandall), which is evenly distributed in all extracellular fluids, but does not penetrate into the cells. The concentration in plasma is then determined, and the extracellular-fluid volume is thus known. Blood-plasma volume is then determined and subtracted from
Fig. 207. Principal chemical constituents of the three body-fluid compartments. Columns on the left correspond to total cation and those on the right to total anion concentration. The figures on the scale are milliequivalents per liter of water.

the extracellular volume; the remainder is the tissue-fluid volume. Usually a dye (T 1824, called Evans' blue) is injected together with the sodium sulfocyanide. Other substances (sucrose, inulin, antipyrine, manitol, radioactive Na or Cl, etc.) have also been used for determining

extracellular-fluid volume. None of the methods so far proposed is completely satisfactory and free from error. The normal amount of tissue fluid found with these methods is 180 to 190 ml. per kg. of body weight. The total amount of body weight has been measured by the administration of deuterium in so-called "heavy" water. The distribution of water in the three compartments of the body is given in Table 55.

Table 55. Distribution of Water in the Body

Fluids	*Liters for adult man of 70 kg. (Gregersen)*	*Liters per 100 kg. of body weight*	
		Gregersen	*Gamble*
Extracellular fluids	17	25	20
Blood plasma	3	4.3	5
Tissue fluids	14	18–20	15
Intracellular fluids	29	41	50
Total	46	66	70

The passage of water through the body. Ingested water takes the following path: (*a*) it is absorbed; (*b*) it is transported in blood plasma; (*c*) it diffuses out of the blood capillaries into the tissue fluids; (*d*) it diffuses into the cells; (*e*) it diffuses from the cells back into the tissue fluids; (*f*) it diffuses from the tissue fluids into the blood plasma; (*g*) it is finally eliminated by the kidney, skin, lungs, intestine, etc.

From 3 to 10 liters per day of water is poured into the digestive tract in saliva, in gastric, pancreatic, and enteric juice, and in bile, but most of it is reabsorbed. From 700 to 1,500 cc. of lymph is poured into the blood every 24 hr.

Ingestion of a large quantity of water may cause dilution of the blood, usually of not more than 5 per cent, seldom up to 15 per cent. Dilution occurs in 20 to 40 min. after water has been drunk, and in 50 to 80 min. blood concentration has returned to the initial level. Water is not stored in the blood; it diffuses rapidly into the tissue fluids, and later is eliminated by the kidney.

Not only water but also substances in solution are constantly being interchanged between the three compartments of the body. There is a dynamic osmotic equilibrium between the three compartments which plays an important part in this interchange. The movement of fluid and solutes is caused mainly by

1. The difference in hydrostatic pressure between the capillaries and the tissue fluids. The former is usually greater in the arterial end of the capillary, and water flows out from the blood into tissues.
2. The difference in osmotic pressure between the plasma proteins and the tissue fluids. The former is usually greater and tends to retain water in the blood vessels and to reabsorb it from the tissues, as long as the plasma-protein concentration and the permeability of the capillary membrane remain normal.

Changes in the sodium balance accompany or provoke changes in the water balance. Thus, when sodium is lost, water is also lost and anhydremia occurs. On the other hand, retention of sodium causes retention of water; this is why sodium chloride or bicarbonate solutions are injected into subjects with anhydremia. Changes or disturbance in the potassium balance arise in changes in cell metabolism (Peters).

Potassium and calcium salts are not retained in the body as is the case with sodium salts, because these salts, after having filtered through the glomeruli in the kidneys, are not reabsorbed by the renal tubes; they diminish the reabsorption of water in these tubes, thus having a diuretic effect (see Urinary Secretion). Acidosis also increases diuresis and leads to dehydration. In therapeutics this effect of acidosis is sometimes utilized and ammonium chloride is given in order to provoke acidosis and cause dehydration.

REGULATION OF WATER METABOLISM

Mechanisms. The concentration of water in the body is kept constant within narrow limits. There is an equilibrium between mechanisms that tend to hydrate the organism and others that tend to eliminate excess of water. The body can be hydrated much more rapidly than water can be eliminated.

Water lost by the body is replaced by water absorbed from the digestive tract or, in amphibians and aquatic animals, through the skin. Normally man replaces water by drinking it, and the intake is regulated by the sensation of thirst. Water, however, is also used if it is injected subcutaneously or intravenously. Absorption, transportation, and elimination of water are

regulated by nervous and humoral mechanisms, in which the intestine, liver, and kidney play a leading part; acid-base and ionic equilibriums are also important.

Thirst. The impulse to drink, thus replenishing the water in the body, is induced by the sensation of thirst. It is usually well regulated, and a dog ingests in 2 minutes the exact amount needed to restore water lost (Adolph). Thirst is caused by a decrease in body water due to (*a*) deprivation of fluids; (*b*) loss of water owing to copious sweating, diarrhea, or polyuria; (*c*) hemorrhage, which provokes the passage of water from the tissues to the blood; (*d*) intravenous injection of hypertonic solutions or ingestion of salt, etc.

Thirst has been attributed both to local dehydration of certain tissues and to the general dehydration of the body. General dehydration, by modifying the concentration of salts and water in the blood, is supposed to act on certain nerve centers, thus provoking thirst. Others suppose that dehydration of the cells stimulates afferent nerve endings, which carry impulses to nerve centers and provoke thirst.

Cannon[1] and Gregersen[2] attribute thirst to drying of the mucosae of the mouth and pharynx, especially of the fauces, owing to a decrease in the secretion of saliva. Decrease in salivary secretion has been observed in anhydremia, hemorrhage, injection of hypertonic saline solution, and other conditions in which there is dehydration. In these cases thirst disappears if the mucosae of the mouth and pharynx are wetted, but thirst soon reappears because this water rapidly evaporates and is not replaced, as salivary secretion does not increase while the blood remains dehydrated.

The theory that attributes thirst to general dehydration of the tissues is supported by Claude Bernard's experiments on horses with a fistula in the esophagus and dogs with a gastric fistula. These animals drank continuously, stopping only to rest for a few moments; their thirst was never satisfied, because the water drunk was lost through the fistula. If 500 to 1,000 cc. of water was introduced by a catheter into the stomach, thus preventing its loss, thirst was soon appeased. Thirst can also be slaked by intravenous injection of water (Orfila) or isotonic saline. An increase in the osmotic pressure of the blood plasma, such as is observed in diabetic hyperglycemia or after hypertonic salt injection, provokes thirst. Cell dehydration would be the cause of the desire for water, according to Gilman, Dill, and others. So far this theory has not been demonstrated by direct experiments, and it does not explain all the facts observed.

[1] Cannon, W. B., *Proc. Roy. Soc., London, s.B.*, **90**, 283, 1918.

[2] Gregersen, M., in MacLeod, "Physiology in Modern Medicine," 9th ed., Mosby, St. Louis, 1941.

Bellows's[1] observations on dogs with a fistula in the esophagus tend to conciliate the theories that attribute thirst to a local cause with those which consider that it is caused by a general dehydration of the tissues. By wetting the mouth and pharynx, thirst was appeased immediately for a short time. By introducing water into the stomach, thirst was appeased after a certain delay, and the effect lasted for some time.

The importance of certain nerve centers will be discussed when considering the neurohypophysis and the hypothalamus.

Changes in water and electrolyte concentration in the three compartments (blood plasma, tissue fluids, and intracellular fluids), occurring in thirst due to different causes, are not yet sufficiently well known for their significance with respect to the sensation of thirst to be understood.

The part played by different organs in the regulation of water metabolism. Water is absorbed mainly in the small intestine and to a lesser degree in the large intestine. The liver can store water, and certain disturbances in the circulation of the liver cause a decrease in diuresis. In some forms of hepatosis and cirrhosis there is a delay in diuresis after the ingestion of water (opsiuria). An antidiuretic factor has been found in the plasma and urine in patients with a diseased liver; the effect of this organ on water metabolism is, therefore, not exerted only by physical means.

The kidney plays an important part in water metabolism. Approximately 170 liters of fluid passes daily through the glomeruli, and 168.5 liters is reabsorbed in the renal tubes; 1.5 liters is eliminated as urine. Excess water is eliminated by the kidney. Moreover, the kidney eliminates selectively water or salts so as to keep constant the osmotic pressure in the body fluids.

The neurohypophysis secretes an antidiuretic hormone which regulates the absorption of

[1] Bellows, R. T., *Am. J. Physiol.*, **125**, 87, 1939.

water in the distal renal tubes. Secretion of this hormone is under the continuous control of the supraoptic nuclei, which send fibers in the tractus supraopticohypophysis through the hypophyseal stalk to the neurohypophysis. If the neurohypophysis is removed, or if it is denervated by section of the tractus supraoptico-hypophysis or by destroying the supraoptic nuclei, the antidiuretic hormone is no longer secreted and water is reabsorbed by the distal renal tubes at a lower rate than in normal animals. There is marked polyuria; 5 to 10 liters, and in some cases up to 40 liters, of urine is passed daily. The condition is known as diabetes insipidus. Such considerable loss of water causes an intense thirst and the ingestion of large quantities of water (polydipsia). If the subject abstains from drinking water, his blood concentration increases (anhydremia). Administration of posterior hypophyseal extract increases reabsorption by the renal tubes, diminishes diuresis, and causes the signs of diabetes insipidus to disappear. In normal subjects posterior lobe extracts diminish spontaneous diuresis and diuresis following the ingestion of water.

Corticoadrenal hormones regulate the reabsorption of sodium by the renal tubes. Adrenalectomy causes loss of sodium in the urine, accompanied by chloride and water (polyuria). Potassium, on the contrary, is reabsorbed at a greater than normal rate. These abnormalities in renal excretion cause a decrease in plasma sodium and chloride and in extracellular-fluid volume, with a decrease in blood-plasma volume (hemoconcentration). At this stage of adrenal insufficiency there is no longer polyuria but oliguria. Ingested water is eliminated very slowly in adrenal insufficiency, a fact which has been used to establish the diagnosis of this condition. Administration of certain corticoadrenal hormones increases reabsorption of sodium, chloride, and water and decreases reabsorption of potassium in the renal tubes. Therefore in cases of adrenal insufficiency treated with these hormones excess excretion of sodium and chloride in the urine ceases and Na and Cl concentration in plasma increases and that of K decreases. Desoxycorticosterone has these effects and maintains life in adrenalectomized animals. An excess of this hormone causes polyuria and polydipsia. If the diet contains large quantities of NaCl at the same time as this hormone is given, salt and water are retained in the extracellular fluids, and plethora, edema, hypertension, and cardiac insufficiency may follow.

Estrogenic hormones can provoke some retention of NaCl and water. This is observed in the sexual skin of female monkeys. In women there is frequently a slight periodic premenstrual increase in weight, and sometimes edema. If the ingestion of salt is restricted this increase is not observed.

The thyroid plays an important part in water metabolism. In thyroid insufficiency water is retained together with protein and infiltrates the skin (myxedema). Administration of thyroid causes an increase in diuresis and loss of body weight during a few days, particularly marked in myxedematous subjects, until an equilibrium is established. Polyuria is also observed when the thyroid is stimulated by the thyrotrophic hormone of the hypophysis.

DISTURBANCES IN WATER METABOLISM

Water metabolism is disturbed in the following circumstances:

1. When water is lost in relatively larger amounts than salt, as occurs in deprivation of water, copious sweating, and diabetes insipidus.
2. When the loss of salt is relatively greater than the loss of water, as in acute adrenal insufficiency, diabetic acidosis, and copious loss of fluid through the stomach or intestine.
3. When salt and water are lost in equivalent amounts, as in fasting.
4. When salt is retained in excess of water, as when sea water is drunk.
5. When water is retained in excess of salt, as in water intoxication (see page 476).
6. When salt and water are retained in equivalent amounts, as in edema.

Edema is due to excessive accumulation of tissue fluid, sometimes accompanied by effusion in the serous cavities. It is observed in cardiac decompensation, in cases of obstruction of the venous circulation, in cirrhosis of the liver, and in malnutrition (hypoproteinemia, some forms of kidney disease, etc.).

Dehydration. In true dehydration the water content of the body is diminished, *i.e.*, there is a deficiency of water. It should be distinguished

from salt deficiency, although the two conditions are frequently associated.

Subjects deprived of food but not of water survive much longer than those deprived of food and water. Luciani mentions a political prisoner who went on total food strike and drank no water; he survived 17 days. After a few days hunger was no longer felt, but he suffered from an intense thirst until shortly before he died. In the hot, dry climate of a desert, death occurs after 36 to 72 hr. of total water deprivation. Experimental data have established that a loss of water equivalent to 10 per cent of the body weight causes serious disturbances; a loss of 20 to 25 per cent is usually fatal.

The following signs are observed in dehydration: loss of weight; thirst; sunken eyes with softening of the eyeballs; dry lips, tongue, and fauces. The skin is dry; it loses its elasticity and becomes wrinkled. Nonprotein nitrogen Na and Cl concentration in plasma increases; K concentration decreases. There is frequently acidosis. Urinary volume is considerably diminished; the urine is of high density and has a high sodium chloride content. In the final stages there is circulatory collapse.

Acidosis provokes loss of water and anhydremia, which, if sufficiently severe, causes circulatory failure. This occurs in diabetic coma; therefore in the treatment of this condition dehydration must be taken into account. Reciprocally, dehydration (such as occurs in copious diarrhea) can lead to acidosis or to its increase if it is already present.

Sodium chloride deficiency also causes dehydration. There is loss of weight, a dry tongue, sunken eyes with low intraocular pressure, an increase in plasma nonprotein nitrogen, etc. There are, nevertheless, certain symptoms that distinguish this condition from simple dehydration. There is loss of appetite, intense headache, lethargy and even mental confusion, dizziness, and sometimes loss of consciousness; frequently there are painful muscular cramps. All the symptoms of dehydration are present in a severe form, and circulatory collapse is easily provoked. The urine contains little sodium chloride and is of low density, contrasting with the urine of simple dehydration, which has a high density and NaCl concentration.

Salt deficiency is observed when intense manual labor is performed in a hot climate, because NaCl is lost in sweat. Water is usually drunk in sufficient quantities to replace the loss of water, but sodium chloride is not replaced. After a few days, weight is lost, there is anhydremia, and blood NaCl concentration is decreased. The signs of deficiency disappear as soon as NaCl is ingested; they can be prevented by adding 0.1 per cent NaCl to the drinking water. Water alone does not improve the subjects; on the contrary, copious water drinking increases sweating and the loss of NaCl, thereby increasing the seriousness of the condition.

Simple anhydremia is rapidly cured by drinking water. In other cases of anhydremia, sodium chloride (0.7 to 0.9 per cent) should also be given, and when there is hypochloremia, KCl and sodium bicarbonate should be added. Mortality in infantile diarrheas is considerably diminished by adequate treatment with salts and water (see Chap. 45, Mineral Metabolism).

Water intoxication. If the kidney is functioning normally, excessive ingestion of water is well tolerated, because the excess is rapidly eliminated in the urine, and hydremia is prevented or occurs in only a mild form. If the kidney is diseased, copious water drinking causes a disturbance known as water intoxication. There are headache and general malaise, vomiting, painful muscular cramps, an increase in body weight, and a rise in blood pressure. In the dog, water intoxication has been provoked by giving large quantities of water (50 cc. per kg.) by stomach tube and injecting antidiuretic posterior hypophyseal extract. In these animals there are asthenia, restlessness, salivation, vomiting, diarrhea, tremor, clonic muscular contractions and convulsions, lethargy, coma, and finally death. At autopsy cerebral edema is frequently found.

Excessive ingestion of water, especially if antidiuretic hormone is given, causes convulsive attacks in epileptic patients.

In pregnancy retention of water may lead to eclampsia with fatal convulsions.

CHAPTER 45

Mineral Metabolism

WATER AND SALTS are the inorganic or mineral constituents of the body. They fulfill specific functions in the cells and are indispensable for life. Each type of cell has a particular mineral composition and water content, which is kept constant within narrow limits. Some mineral substances, *e.g.*, sodium chloride, are found in relatively large quantities; they take part in maintaining the osmotic pressure and acid-base equilibrium. Others are found in very small quantities but may be of great physiologic importance; *e.g.*, iodine, which is indispensable for normal thyroid function.

Biologic activity of minute quantities of metals (*oligodynamic effect*) was first demonstrated by Raulin in his classic experiments on the growth of *Aspergillus*.

Oxygen, carbon, hydrogen, and nitrogen in water and organic substances form approximately 95 per cent of the human body. Calcination reduces the body to ashes, which weigh 4.5 to 5 per cent of the total body weight. According to Bertrand,[1] 36 chemical elements have so far been found in animal organisms; 29 are always present, 7 are occasionally found. Among those always present are 13 nonmetals (C, H, O, N, S, P, Cl, F, Br, I, B, As, Si), and 16 metals (Na, K, Ca, Mg, Fe, Zn, Cu, Ni, Co, Mn, Al, Pb, Sn, Mo, Va, Ti). Those occasionally found are Rb, Cs, Li, Ba, Sr, Ag, and Cr (Table 56).

Table 56. Principal Constituent Elements of the Human Body

Constituent element	Percentage of body weight	Constituent element	Percentage of body weight	Constituent element	Percentage of body weight
Oxygen	65	Calcium	2	Magnesium	0.05
Carbon	18	Phosphorus	1	Iron	0.005
Hydrogen	10	Potassium	0.35	Manganese	0.0003
Nitrogen	3	Sulfur	0.25	Copper	0.00022
O, C, H, and N	96	Sodium	0.24	Iodine	0.00004

Data taken from Volkman, Sherman, Widdowson, and McCance, *et al.*

Mineral substances are found in extracellular and intracellular fluids; their concentrations are maintained constant by means of regulatory mechanisms in which the kidneys, lungs, erythrocytes, and tissues play a part. They are important factors in the following functions:

1. Osmotic equilibrium.
2. Acid-base equilibrium.
3. Ionic equilibrium (Na^+, K^+, Ca^{++}, Mg^{++}), which is an important factor in the excitability of nerve and muscle, capillary and cell permeability, cardiac functions, etc.
4. Water metabolism and exchange of water between blood plasma and extracellular and intracellular fluids.
5. Enzymatic systems (Mg^{++} of phosphatase, carboxylase, cozymase; Mn^{++} of arginase, cholesterinase, Zn^{++} of carbonic anhydrase).
6. Respiratory function, by means of the part played in carrying CO_2 from the cells to the lung, and of Fe in ferroporphyrins (hemoglobin, myoglobin, cytochrome).

[1] BERTRAND, G., Congrès Chim. Biol., Paris, 1937.

7. As constituents of tissues, especially bone (mainly calcium and phosphate), to which they give consistency in life and duration after death.
8. Thyroid function. Iodine forms part of the thyroid hormone which regulates oxygen consumption and heat production.

Excretion. Sodium, chloride, and potassium are eliminated mainly by the kidney, which excretes 95 per cent of the potassium. These elements are ultrafiltrated into the glomerular fluid and are then in great part reabsorbed by the renal tubes. Approximately 180 liters of fluid, containing 1,200 gm. of NaCl, is filtered daily through the glomeruli, but most of this is reabsorbed and only 1.5 liters of water with 5 to 10 gm. of NaCl is eliminated in the urine. The kidney is the main organ of regulation of electrolyte concentration and water in the body; therefore it also regulates osmotic pressure, and ionic and acid-base equilibriums. Acids combined with sodium and other bases in blood plasma are combined with ammonium in the kidney and excreted in the urine as ammonium salts, while most of the base is reabsorbed and returned to the plasma.

Table 57. Electrolyte Concentration in Body Fluids of Man in Milliequivalents* per Liter

Body fluid	Na^+	K^+	Ca^{++}	Mg^{++}	Cl^-	HCO_3^-	$PO_4^{=}$	SO_4^-	*Organic acid*
Intracellular fluid	40	118	3	20	21	10	110	1	...
	37	112	..	..	25	...	...	...	...
Tissue fluid	138	5	5	3	108	27	2	1	6
Blood plasma	142	5	5	3	103	27	2	1	6

* The advantage of expressing electrolyte concentration in milliequivalents is explained on page 9.

DISTRIBUTION OF ELECTROLYTES IN THE BODY FLUIDS

The electrolyte content of body fluids in the three compartments is given in Table 57.

Tissue fluid varies considerably in the different tissues, but the composition of blood plasma is maintained constant. Blood plasma has a relatively high concentration of Na and Cl; this is also true of tissue fluids, which, however, have a lower protein concentration. Intracellular fluid has a high concentration of K^+, Mg^{++}, $PO_4^{=}$, and protein, and low concentrations of Na^+, Cl^+, and HCO_3^-.

METABOLISM OF SODIUM, CHLORIDE, AND POTASSIUM

Requirement and ingestion. Complete deprivation of any of these three elements causes growth to cease and eventually the animals die. Deficiency in human beings is seldom seen because the diet usually contains them in adequate amounts. There is a daily ingestion of 5 to 15 gm. of sodium chloride, but a normal balance can be maintained with 2 to 3 gm. daily. A normal diet provides 4 to 6 gm. of sodium and 2 to 4 gm. of potassium daily. Special diets poor in either of these elements can be prepared easily, as there are tables which give the sodium and potassium content of different foodstuffs. During growth there is greater need of potassium because large amounts are retained in the protoplasm, especially in young cells.

Elimination of sodium chloride from the diet causes a decrease in sodium chloride concentration in plasma. The normal average level is 600 mg./100 cc. (580 to 620 mg. per cent); when this falls to 560 mg. per cent, urinary excretion of sodium chloride diminishes and is soon reduced to traces, or it may even cease completely. Simultaneously there is a decrease in sodium chloride and hydrochloric acid excreted in the gastric juice. If, on the contrary, an excess of sodium chloride is ingested, it is eliminated in one to two days. Sodium chloride is retained only when there has been a deficiency of this salt or when there is anhydremia or a tendency to form edema. Potassium is eliminated at a faster rate than sodium. The use of isotopes has shown that the passage of sodium through the organism takes place at a rapid rate. A normal subject exchanges about half the total sodium content of the body in approximately 15 days.

Sodium is the cation in highest concentration

in plasma; it is in equilibrium with Cl^-, HCO_3^-, fixed acids and protein. Sodium combined with bicarbonate is available for neutralization of acids and is therefore known as the alkaline reserve of the plasma.

The concentration of all bases in plasma is 155 mEq./liter. Sodium constitutes 92 per cent of total base, and Cl^- makes up two-thirds of the anions.

Changes in acid-base equilibrium are caused by a deficiency in one of the ions in extracellular fluids. Thus Cl^- deficiency causes alkalosis and Na^+ deficiency causes acidosis. For example, loss of Cl^- by repeated vomiting produces alkalosis; loss of alkali by a pancreatic, biliary, or intestinal fistula causes acidosis.

Sodium chloride is the main factor in maintaining osmotic equilibrium. Retention of Na and Cl causes the retention of water, and retention of water causes Na and Cl to be retained. Excretion of Na and Cl is accompanied by the excretion of water, and the elimination of large quantities of water is accompanied by excretion of Na and Cl. Thus, when a solution of glucose is injected, glucose is metabolized and the excess water eliminated carries sodium chloride with it. A decrease in extracellular sodium causes water to pass into the cells which become swollen.

A normal Na and Cl concentration in the blood plasma is of great importance to the organism. Adrenalectomized animals survive as long as NaCl is given them in sufficient amounts to compensate the loss of Na; as soon as the salt treatment is discontinued they fall into acute adrenal insufficiency and die. In Addison's disease (adrenal insufficiency in man) salt treatment also prevents and cures acute adrenal crises and prolongs life.

Subjects performing heavy labor in a hot environment sweat profusely and lose NaCl. They suffer from tiredness, insomnia, and painful muscular cramps. These symptoms are prevented by adding 0.1 to 0.2 per cent NaCl to the drinking water or by the ingestion of salt tablets.

Edema consists in the accumulation of sodium chloride and water in the subcutaneous tissue; therefore Na, Cl, and water are retained in the body. In these cases ingestion of NaCl causes an increase in edema owing to further retention of salt and water. Elimination of NaCl, on the contrary, causes loss of water and diminishes edema. Most diuretic substances decrease reabsorption of NaCl and water in the renal tubes, thus increasing urinary elimination of these substances.

Large amounts of sodium, chloride, and potassium can be lost and anhydremia provoked by (*a*) profuse sweating, polyuria, diarrhea, vomiting, loss of fluid from fistulas in the digestive tract; (*b*) acidosis due to excess renal excretion of salts and water; (*c*) rapid transudation of water and salts in surgical and traumatic shock, pulmonary edema, acute intoxication with mercury, etc. (see Chap. 44, Water Metabolism).

Ingestion of ion-exchange resins which adsorb sodium and potassium may cause a considerable loss of these elements through the digestive tract. This principle has been used in therapeutics for reducing edema, etc., but care should be taken that not too much potassium is lost.

Corticoadrenal hormones control reabsorption of sodium in the renal tubes. In acute adrenal insufficiency this reabsorption diminishes, therefore renal excretion of sodium, chloride, and water increases and that of potassium diminishes. Sodium and chloride concentration in plasma diminishes, and potassium concentration increases. Corticoadrenal extract and desoxycorticosterone reverse these conditions: Na and water are retained, and renal excretion of K increases; in blood plasma, Na and Cl concentrations return to normal and that of K decreases. An excess of desoxycorticosterone in patients with adrenal insufficiency and even in normal subjects may cause excess retention of Na and Cl, which provokes retention of water and subsequent edema, hypertension, and cardiac dilatation (see Chap. 54, The Adrenal Glands).

In heart insufficiency there is congestion of the kidneys, which, according to some authors, increases glomerular filtration and tubular reabsorption of Na. Water would also be reabsorbed, thus increasing plasma volume and venous and capillary pressure. Finally, transudation of fluid from plasma to the tissues would take place, with formation of edema (Stead). According to others, mechanical factors (*i.e.*, increased venous and capillary pressure) are the main cause of edema in cardiac disease.

Salt-poor diets, *e.g.*, Kempner's rice diet, have been used in the treatment of hypertension.

Ingestion of potassium salts causes diuresis because elimination of K in the urine diminishes reabsorption of Na, Cl, and water by the renal tubes.

Mercurial diuretics diminish tubular reabsorption of Na and Cl which carry water away with them, thus causing an increase in urinary volume.

In certain forms of acute nephritis glomerular filtration diminishes, Na is retained and there is a tendency to form edema.

The role of potassium. Potassium is the predominant cation in the cells. It is the main factor in osmotic equilibrium and acts as available base in acid-base equilibrium; it is a constituent of essential enzymatic systems and plays a part in electrical phenomena. Changes in potassium concentration have a marked influence on most of the functions of the cells.

A 70-kg. man has approximately 170 gm. of potassium, of which 9 gm. is in the blood (only 0.6 gm. in plasma), and 3 gm. in tissue fluids. Potassium is found in relatively large amounts in cells, *e.g.*, in muscle and liver cells and in erythrocytes (400 mg./100 ml.), and in much smaller quantities in extracellular fluids, *e.g.*, 17 mg./100 ml. in blood plasma if the erythrocytes are separated without delay. This high intracellular concentration of potassium is maintained against osmotic and electrical forces by mechanisms which are not yet well understood. Studies with isotopes of potassium have shown that it is continuously entering the cells and leaving them and that a dynamic equilibrium maintains a constant concentration.

The concentration of potassium in blood plasma is small but of great physiologic importance, because it is in ionic equilibrium with Na, Ca, and Mg, so that when it increases or diminishes it has a marked effect on many functions of the cells. Variations of plasma-potassium concentration are therefore of great interest, and they can be rapidly and accurately determined by means of chemical analysis or the flame photometer. The level of potassium in plasma, however, cannot be taken as reflecting its concentration in the cells, because these may be depleted of potassium although the plasma level remains within normal range.

When potassium leaves the cells it is replaced by sodium. There is a transitory outward migration during activity in muscle and nerve, and a rapid return during the phase of recovery. Glycogenolysis is also accompanied by a loss of potassium, and glycogenesis by accumulation within the cells. Hypoxia or anoxia and other agents which damage the cell provoke loss of potassium. Diets with low potassium content cause a marked and sustained decrease in potassium concentration of muscle. Potassium is accumulated during normal growth and during growth provoked by testosterone and somatotrophin.

Potassium deficiency may be due to

1. Insufficient amount in the diet.
2. Loss in digestive secretions owing to vomiting, diarrhea, and fistulas. Up to one-quarter the total amount in the body may be lost in cases of profuse diarrhea.
3. Increased renal secretion as in diabetic acidosis, abundant diuresis caused by injection of glucose or saline solutions, or excess administration of corticoadrenal hormones (desoxycorticosterone).
4. Increased protein catabolism.
5. Injecting fluids without potassium (glucose, sodium chloride solutions, etc.), which can provoke or increase deficiency in cell potassium.

Potassium deficiency may cause a fall in plasma potassium; this also occurs when the cells take up potassium at a rapid rate, *e.g.*, after the injection of glucose, insulin, or small doses of adrenaline and in familial periodic paralysis. An excess of corticoadrenal hormones provokes loss of K and Cl, consequently alkalosis with hypopotassemia and hypochloremia; this is seen in some cases of hypercorticalism, Cushing's disease, and after injection of adrenocorticotrophin. A slight decrease in plasma potassium has been observed in the course of hypophyseal insufficiency in the dog, and a transitory fall during anesthesia.

A fall in the concentration of plasma or intracellular potassium if sufficiently marked will cause loss of appetite, meteorism, lethargy, muscular weakness leading to paralysis, dilatation of the heart, hypotension, and pulmonary edema. A prolonged fall may produce foci of necrosis in the myocardium and other tissues. The electrocardiogram shows a low and wide T wave, lengthening of the QT and sometimes the PR intervals, and ST depression when the plasma concentration falls to 10 to 12 mg./100 ml. (2.5 to 3 mEq./liter).

Potassium deficiency is treated by the administration of potassium, preferably by mouth. If it must be injected, it should be by slow intra-

venous infusion of balanced solutions with more Na than Cl, taking care to remain well below toxic levels. Treatment by infusion of balanced solutions has lowered considerably the mortality in cases of diabetic coma and infantile diarrheas.[1]

An increase in plasma potassium to 30 mg./100 ml. or more has toxic effects which may cause death. Plasma potassium increases in the following cases: (*a*) when an excess of K is incorporated into the organism; (*b*) when there is renal insufficiency (deficient elimination of K) and the intake is not reduced or suppressed; (*c*) when there is an increase in protein catabolism, cytolysis or cell injury as in hemolysis, trauma, hypoxia, ischemia, or shock; (*d*) when there is strong, sustained, and widespread muscular contraction, *e.g.*, tetanus, convulsions (during contraction K goes out of the muscle fibers, and returns during recovery); (*e*) when the sympathetic system is stimulated or adrenaline is injected or secreted in sufficiently large quantities (K is released from the liver to return during the period of recovery—sympathico-adreno-hepatic mechanism); (*f*) in dehydration owing to an increase in concentration of extracellular fluid; (*g*) in severe uncompensated corticoadrenal insufficiency, but not in compensated insufficiency (renal excretion of K diminishes and K increases in extracellular fluids but diminishes within the cells).

When plasma potassium increases, the electrocardiogram shows a high and narrow T wave, lengthening of PR interval, and depression of ST; P may disappear, and the QRST complex may show abnormalities. The heart stops in diastole when K concentration in plasma rises to 39 mg./100 ml. (10 mEq./liter).

Potassium can be removed from the organism by hemodialysis or by oral administration of ion-exchange resins.

CALCIUM METABOLISM

Functions of calcium. Calcium makes up about 2 per cent of the body weight; most of it (98 per cent) is in the bones. It has many functions, among which the following are the most important: (*a*) it is an essential factor in the development of bones and teeth, which owe their consistency to calcium salts; (*b*) it is an important factor in the regulation of membrane permeability;[1] (*c*) it is essential for nearly all the functions of the cell; (*d*) in ionic equilibrium with Na, K, and Mg, it regulates neuromuscular excitability; (*e*) it is a necessary factor in blood clotting and milk coagulation; (*f*) it plays a part, although only a secondary one, in the regulation of water metabolism and acid-base equilibrium. Calcium is closely associated with phosphorus in the process of ossification. Variations in blood-calcium concentration are generally in the opposite direction to those in blood-phosphorus concentration. Thus hypocalcemia is usually accompanied by hyperphosphatemia, and hypercalcemia by hypophosphatemia.

The important factor in the regulation of cell functions and neuromuscular excitability is the concentration of calcium ion, not of total calcium. Calcium ion depresses excitability, but its effect depends on the concentration of other ions. Monovalent ions (Na^+ and K^+) have the opposite effect of bivalent ions (Ca^{++} and Mg^{++}); hydrogen ion has the same effect as bivalent ions. Excitability depends on an equilibrium between these ions, which can be expressed as follows:

$$K = \frac{(Na^+) + (K^+)}{(Ca^{++}) + (Mg^{++}) + (H^+)}$$

Excitability is depressed when the value of the constant K diminishes and it becomes higher as K increases.

Hypocalcemia (*i.e.*, total blood Ca concentration below normal) is accompanied by a decrease in Ca ion concentration; the ionic equilibrium is disturbed, and excitability increases. Neuromuscular hyperexcitability causes an increase in muscle tonus, muscular spasms, tremor, and in some cases convulsions. This condition is known as tetany. Hypercalcemia, on the contrary, depresses excitability in the peripheral tissues and in the nerve centers.

Tetany. Neuromuscular hyperexcitability is produced in several ways: (*a*) fall in blood calcium; (*b*) injection of phosphate, which provokes a fall in blood calcium; (*c*) injection of citrate, which causes a decrease in Ca ion; (*d*) alkalosis due to excessive ingestion of bicarbonate or loss of Cl in repeated vomiting (gastric tetany); (*e*) alkalosis provoked by hyperpnea; (*f*) decrease in magnesium; (*g*) certain nerve poisons, such as

[1] Darrow, D. C., *Bull. New York Acad. Med.*, **24**, 147, 1948.

[1] Calcium diminishes membrane permeability; it also diminishes hydration of colloids, and renders gels firmer; potassium and sodium have the opposite effects.

guanidine and ergot. Table 58 summarizes the condition of the blood in different types of tetany.

Ingestion and requirement. Calcium forms part of a normal diet. Milk (0.15 per cent), cheese (0.5 to 1 per cent), and green vegetables, if they have not been deprived of Ca by boiling, are the foodstuffs that contain the most calcium. Certain mineral waters also have a high calcium content. There is a very large store of calcium and phosphorus in the bones. Ca and P are continuously entering and leaving this store, and there are precise mechanisms that regulate this interchange and maintain an equilibrium in calcium metabolism. This equilibrium is dependent on (*a*) calcium ingested; (*b*) calcium excretion; (*c*) regulatory factors, the most outstanding of which are vitamin D and the parathyroid hormone. The concentration of calcium in the blood is not a reliable index of calcium metabolism, which can be estimated only by measuring the calcium balance (*i.e.*, calcium intake and output) and examining the condition of the bones by means of radiographs, histologic examination, and chemical analysis.

The minimum daily calcium requirement is 0.45 gm., according to Sherman; but the normal diet for an adult should contain approximately twice this amount, *i.e.*, 1 gm. Ca requirement increases in pregnancy and lactation, owing to the formation of the bones in the fetus and the secretion of milk; pregnant women should receive 1.5 gm. daily and lactating women 2 gm. daily. If there is an insufficient Ca intake the mother's bones are decalcified, and even so the child's bones and teeth may be deficiently calcified and suffer permanent damage. Children should be given 1 gm. of Ca daily between the ages of 1 and 12 years. Girls should have 1.3 gm. from 13 to 15 years and 1 gm. from 16 to 20 years; boys, 1.4 gm. from 13 to 20 years.[1]

Table 58. Types of Tetany

Cause	*Concentration in blood plasma*				*pH*
	Ca	*Ca^{++}*	*PO_4*	*CO_3H^-*	
1. Calcium deficiency					
a. Rickets and osteomalacia*	Reduced	Reduced	Reduced	Normal	Normal
b. Insufficient Ca intake	Reduced	Reduced	Increased	Normal	Normal
c. Oxalate	Reduced	Reduced	?	Normal	Normal
d. Intestinal (sprue, celiac disease)	Reduced	Reduced	?	Normal	Normal
e. Parathyroid	Reduced	Reduced	Increased	Normal	Normal

3. Bicarbonate	Normal	?	?	Increased	Increased
4. Hyperventilation	Normal	?	Normal	Normal	Increased
5. Citrate	Increased	Low	?	Normal	Normal
6. Toxic, guanidine	Increased	Normal	?	?	?
7. Magnesium deficiency	Normal	Normal	Normal	Normal	Normal

Source: After Shohl.
Tetany is due to decrease in total Ca and Ca ion (1 and 2); alkalosis (3 and 4); decrease in Ca ion (3 and 5); a toxic factor (6); and decrease in Mg (7).
* Tetany is not always present.

Calcium deficiency is by no means exceptional in human diets. It causes (*a*) disturbances in growth and development, digestive disturbances, sterility, and premature death; (*b*) osteoporosis; (*c*) slight or moderate hypocalcemia; (*d*) in some cases, hyperexcitability or even tetany.

Absorption. Calcium is absorbed from the duodenum and other parts of the small intestine. Calcium absorption is conditioned by three principal factors: (*a*) vitamin D; (*b*) the presence of other substances; (*c*) the pH of the intestinal content. Vitamin D increases absorption of Ca; it is an essential factor in the nutrition of children. Calcium salts that are soluble in water are absorbed more readily than water-insoluble calcium salts, which must first be dissolved in the intestinal content.

[1] FOOD AND NUTRITION BOARD, NATIONAL RESEARCH COUNCIL, *J. A. M. A.*, **116**, 2601, 1941.

An acid medium in the duodenum is of great importance in calcium absorption. Thus, in puppies, gastrectomy causes deficient absorption of Ca, the bones do not develop normally, and the animals become bowlegged (Ivy *et al.*). Children absorb 50 to 70 per cent of the Ca in mother's milk, but only 30 to 35 per cent of that in cow's milk. A high-protein diet favors the absorption of Ca, because calcium phosphate and carbonate are more soluble in a solution of amino acids than in water.[1] Bile and sugars (lactose) also favor calcium absorption. The absorption of fat increases that of Ca, but when fats are not absorbed, insoluble calcium soaps are formed in the intestine and Ca is thus lost in the feces. Soluble calcium salts given therapeutically should be taken outside the digestive periods.

Calcium absorption is deficient in children when the diet does not contain vitamin D or when substances are ingested that combine with Ca and form insoluble calcium salts. For example, when there is steatorrhea (fatty diarrhea), insoluble calcium salts are formed and Ca is not absorbed. When alkali, phosphate, or oxalate is ingested, Ca is not well dissolved or absorbed. The unfavorable effect of cereals on calcium metabolism (Mellanby, 1925) is due to phytic acid, which forms insoluble calcium, magnesium, and iron salts and prevents the absorption of these elements (McCance). The unfavorable effect of black bread or 85 per cent milled flour on calcium absorption should be compensated by adding 1 gm. or more of Ca per kg. of these foodstuffs.[2]

Excretion. The intestine excretes approximately two-thirds (50 to 90 per cent) of the calcium output. The remaining third is eliminated by the kidney— 30 to 50 per cent if the diet does not contain much Ca, and 10 to 20 per cent if it does. The daily excretion of Ca is usually 0.4 to 0.8 gm. in the feces and 0.15 gm. in the urine. Large amounts of Ca are secreted with the digestive juices, but most of this is reabsorbed. Renal excretion of Ca is closely related to the calcemic level. When blood calcium falls below 8.5 mg. per cent, urinary calcium diminishes, and there is little or no Ca in the urine when the blood Ca level is below 6.5 mg. per cent. Hypercalcemia increases calciuria and the proportion of total Ca eliminated by the kidney. Lactating females excrete large quantities of Ca in the milk, which should be replaced by increasing the calcium in the diet.

Calcium excretion increases considerably in hyperparathyroidism; it is high in hyperthyroidism and frequently in cases of hyperfunction of the adrenal cortex and the anterior hypophyseal lobe, as occurs in cases of acromegaly and basophil adenoma (Cushing's disease). In the latter there is osteoporosis, which involves the vertebrae and causes curvature of the spine; the bones are soft or brittle, and spontaneous fractures are observed.

Calcemia. Blood plasma contains 9 to 11.5 mg. (average 10 mg.) Ca per 100 cc. There is very little Ca in the erythrocytes (0.5 mg. per cent). Plasma Ca exists in two forms, nondiffusible and diffusible. Nondiffusible Ca (4 to 5 mg. per cent) is not separated from plasma by dialysis or ultrafiltration; it is probably bound to protein. Diffusible Ca (5 to 6.5 mg. per cent) is almost completely dissociated (ionized Ca); less than 0.25 mg. per cent is in the state of nondissociated salt. Ionized Ca concentration can be determined by its effect on the isolated frog's heart.[1] Calcium concentration in the cerebrospinal fluid is almost the same as that of diffusible Ca in plasma; it has therefore been taken as an index of diffusible and ionized Ca in blood. According to McLean and Hastings, blood proteins and Ca are in equilibrium; protein and Ca concentration rise and fall together. Ca ionization is determined by this equilibrium. At 25°C. and pH 7.35, it can be expressed as follows:

$$\frac{(Ca^{++}) \times (\text{protein})}{(\text{Ca proteinate})} = K = 10^{-2.22}$$

Therefore, knowing the protein and Ca concentration of plasma, it is possible to calculate from this equation the Ca ion concentration. A nomogram has been constructed that facilitates calculations.

Variations in calcemia. The blood-calcium level is dependent on (*a*) the amount of Ca absorbed; (*b*) vitamin D in the diet; (*c*) plasma-protein concentration; (*d*) parathyroid function. It is usually inversely related to phosphate concentration in plasma.

Hypocalcemia is observed in the following circumstances: (*a*) deficient absorption or excessive

[1] McCance, R. A., E. M. Widdowson, and H. Lehmann, *Biochem. J.*, **36**, 686, 1942.

[2] Some cereals, *e.g.*, wheat, have phytases that partially destroy phytic acid in the process of baking.

[1] McLean, F. C., and A. B. Hastings, *J. Biol. Chem.*, **107**, 337, 1934; **108**, 285, 1935.

elimination of Ca (moderate or slight hypocalcemia); (*b*) parathyroid insufficiency (marked hypocalcemia); (*c*) some cases of vitamin D deficiency; (*d*) hypoproteinemia (nephrosis) in relation to the fall in plasma-protein concentration (moderate hypocalcemia); (*e*) hyperphosphatemia in some cases of renal insufficiency (moderate hypocalcemia).

Hypocalcemia can be prevented or remedied by the ingestion of calcium; 700 cc. of milk, 11.2 gm. calcium gluconate, and 7.2 gm. calcium lactate contain 1 gm. of Ca. Intravenous injection of calcium salts (*e.g.*, 10 cc. of a 20 per cent Ca gluconate solution, injected very slowly) can be given in cases of emergency, but calcemia soon returns to the initial level. Parathyroid extract provokes a more prolonged rise in calcemia, but after a few weeks of treatment it loses its effect. Large doses of vitamin D and dihydrotachysterol are the most efficient therapeutic agents for producing a prolonged increase in the blood-calcium level and treating cases of decalcification.

Hypercalcemia is observed in the following circumstances: (*a*) immediately after intravenous injection of Ca and for 1 or 2 hours thereafter; (*b*) usually in hyperparathyroidism; (*c*) after the administration of large doses of vitamin D or of dihydrotachysterol (a substance chemically related to vitamin D); (*d*) frequently when there is hyperproteinemia (myeloma); (*e*) in certain cases of bone tumors. Calcium is taken from the bones in *b*, *c*, *d*, and *e*; also when bones are kept immobile in plaster casts.

The Regulation of Calcium Metabolism

Calcium metabolism is conditioned by the existence of a sufficient amount of Ca in the diet, its absorption in the intestine, calcium storage, blood Ca equilibrium, and calcium excretion. Certain accessory food factors, mainly vitamin D, and certain hormones, principally the parathyroid hormone, regulate different aspects of Ca metabolism.

Vitamin D. This vitamin (called the "antirachitic" vitamin) is especially important for the nutrition of the growing child. If the diet does not contain it in sufficient amounts, there are disturbances in the development of the bones and teeth, a condition known as rickets. Vitamin D increases intestinal absorption of calcium and phosphorus and normal calcification of bones and teeth. In rickets there is an insufficient absorption and retention of Ca and P. Blood calcium is usually normal or only slightly diminished, but there is a definite decrease in plasma phosphate. A fall in blood Ca, which causes tetany, is occasionally observed. Large doses of vitamin D or adequate doses of dihydrotachysterol raise the blood Ca level by increasing absorption of Ca and mobilizing bone Ca to some extent; therefore the diet must contain a sufficient amount of Ca to prevent decalcification of the bones when this treatment is applied. Very large doses of either of these steroids provoke hypercalcemia, hypercalciuria, decalcification of the bones, calcium deposits in soft tissues, and other harmful effects that may be fatal.

Vitamin C. In cases of scurvy (vitamin C deficiency), treatment with ascorbic acid (vitamin C) increases the deposition of calcium in the bones. This vitamin is not only a factor in bone calcification; it also conditions the integrity of the protein matrix of bone and the vitality of the osteoblasts.

Parathyroids. Parathyroid hormone regulates Ca metabolism, and more especially the blood-calcium level. Total parathyroidectomy does not modify the absorption of calcium, but it is followed by a decrease in blood calcium, which falls to 7 and even 5 mg. per cent, and by an increase in blood phosphate. Hypocalcemia causes a decrease in the excretion of Ca, especially of urinary calcium. As ionized Ca is also diminished, there is neuromuscular hyperexcitability, which causes spasticity, tremor, and convulsions, *i.e.*, parathyroid tetany.

Tetany is due to hypocalcemia, and all its symptoms rapidly disappear when Ca is administered and the blood-calcium level is raised.

In chronic parathyroid insufficiency there are disturbances in the calcification of the enamel and dentine of teeth and sometimes of bone, and there is deposition of Ca in the crystalline lens of the eye (cataract).

When there is an excess of parathyroid hormone, due either to repeated injections of sufficiently large doses of parathyroid extract or to excessive secretion of the hormone, hypercalcemia is observed. In cases of parathyroid adenoma, there is permanent hypersecretion of parathyroid hormone and a condition known as hyperparathyroidism. In this condition the blood calcium is high and the inorganic phosphorous low; blood phosphate is increased, and

the bones are decalcified. Large doses of parathyroid extract can raise the blood-calcium level to 18 and 20 mg. per cent and provoke signs and symptoms of acute calcium intoxication: anorexia, vomiting, general weakness, and depression, followed by coma and death if hypercalcemia is sufficiently marked and prolonged. In cases of hyperparathyroidism, the renal excretion of Ca and P is increased and sometimes calcium stones are formed in the urinary tract. Calcium and phosphorus are removed from the bones with fibrous degeneration and the formation of cysts (osteitis fibrosa cystica). Decalcification of the bones causes softening and deformation of the skeleton and curvature of the spine, and spontaneous fractures are frequently observed. The calcium requirement is increased, but even with large doses of calcium it is not always possible to obtain a positive calcium balance.

Parathyroid hormone therefore maintains the normal calcium level. Reciprocally, the calcium level regulates parathyroid secretion, which increases when there is hypocalcemia (see Chap. 55).

Thyroid. In thyroid insufficiency the growth of bones (especially in length) is arrested or proceeds at a slower rate than normal. The development of teeth is also abnormally slow. The calcium content of bones and teeth is usually lower in thyroidectomized animals than in controls of the same age. The limbs of growing subjects or animals suffering from thyroid insufficiency are short because of the disturbance in the endochondral ossification of the epiphyseal cartilages.

Hypophysis. Endochondral and periosteal ossification are markedly retarded in anterior hypophyseal insufficiency. Consequently the bones do not develop normally; growth in length is particularly disturbed. There is also dental malformation. Permanent teeth erupt later and grow more slowly than in normal animals; the pulp cavity is large owing to insufficient development of the dentine (Erausquin). In the rat, on the contrary, the pulp cavity is gradually obliterated by calcification of dentine (Schour).

In acromegaly there is excessive development of the bones of the face and cranium, especially of the jawbone, and of the hands and feet, caused by hypersecretion of the anterior hypophyseal growth hormone. In hypophyseal gigantism the bones grow abnormally long. In advanced stages of anterior hypophyseal hyperfunction, calcium excretion is increased. In acromegaly osteoporosis is frequently observed, and the patients become hunchbacked owing to curvature of the spine. In Cushing's syndrome (pituitary basophilism) there are osteoporosis, dorsocervical kyphosis, and frequently spontaneous fractures.

PHOSPHORUS METABOLISM

Functions of phosphorus. There is 450 to 700 gm. of phosphorus in the body of an adult man; 70 to 80 per cent is in the bones and teeth (mainly bound in calcium salts), and 20 to 30 per cent in other tissues. Compounds of phosphorus probably fulfill more varied functions than those of any other mineral element in the organism. Phosphoric acid is an essential constituent of nucleic acids, nucleotides, phospholipids, and hexosephosphates. It is found in many proteins, especially in the so-called "phosphoproteins" such as casein. Some of the most important enzymes are formed by vitamins combined with phosphoric acid; *e.g.*, cocarboxylase is made up of thiamine (vitamin B_1) and phosphoric acid; phosphoriboflavin is one of the respiratory enzymes; coenzymes I and II are nucleotides formed by phosphoric acid, nicotinic amide, adenine, and a pentose. Phosphorylation plays an important part in the selective absorption of sugars and fats. Glycogen is disintegrated into glucose by a process of phosphorolysis, and phosphorylation is the initial step in the synthesis of glycogen from glucose. Phospholipids are the form in which fats are most easily transported and have the highest reactivity. Adenosinephosphate and phosphocreatine in muscle set free large amounts of energy on disintegrating in the course of muscular contraction. Phosphate is the principal anion in intracellular fluids; it plays a part in the regulation of acid-base equilibrium in body fluids and in the urine.

Ingestion and requirement. The diet of a normal adult must contain a minimum of approximately 0.9 gm. of phosphorus to maintain the phosphorus balance in equilibrium; it is nevertheless advisable there should be 50 per cent more (1.35 to 1.4 gm.) as a safety margin. In pregnancy 1.5 to 3 gm. daily is needed to provide for the fetus, which accumulates 40 gm. in the course of intrauterine development. The growing child requires more P than the adult;

80 mg. per kg. is needed by the three-year-old child, 35 mg. per kg. at sixteen years, and 12 mg. per kg. by the adult.

Milk and milk products contain relatively larger quantities of phosphorus than other foods. Moreover, they also contain large amounts of calcium, whereas protein foods such as meat and fish have much phosphorus but little calcium. Meat, liver, eggs, and cereals follow in decreasing order of P content. Phosphorus in cereals is mainly bound in phytin, which is poorly absorbed (McCollum). The diet should have a phosphorus-calcium ratio of 2:1, and care should be taken that this ratio does not fall below 1:1.

Absorption. Phosphorus is mainly absorbed in the upper part of the small intestine. Soluble inorganic phosphates are more readily absorbed than the insoluble inorganic phosphates. Organic compounds of phosphorus are disintegrated by pancreatic or intestinal juice, and the P contained in them is absorbed as phosphate. Vitamin D is an important factor in the absorption of phosphorus; in vitamin D deficiency (rickets), P is absorbed in less than normal quantities. Vitamin D is a factor in the deposition of P in bone, thus decreasing its excretion; this is evident in rickets, in which not only Ca but also P are not stored in the bones and P excretion increases. Beryllium, iron, aluminum, magnesium, strontium, and an excess of Ca diminish the absorption of P, because they form insoluble compounds of phosphorus. Rickets owing to phosphorus deficiency can be produced by ingestion of these minerals.

The administration of a radioactive isotope of P (P^{35}, which has a half life of 14.3 days) has been used to demonstrate the path followed by phosphorus and its fate after it has been absorbed. There is a continuous and rapid exchange of phosphorus in the liver, kidney, and heart; phosphorus absorbed is taken up by these tissues and is retained in part for approximately 30 days. The stores of phosphorus in bone and tissues are not static; on the contrary, there is continuous intake and output of P into and from these structures.

Excretion. A slightly larger proportion of P is eliminated by the kidney than by the intestine. About 60 per cent of total P excreted is found in the urine, and an even larger percentage if stored P is mobilized, as in hyperparathyroidism. In cases of deficient absorption of P (rickets, steatorrhea, celiac disease, etc.), there is relatively more P in the feces than in the urine.

Phosphorus deficiency. Deficient absorption or utilization of P and Ca produces rickets in children and osteoporosis or osteomalacia in adults. The most frequent cause of these disturbances is vitamin D deficiency, but they may be due to insufficiency of P in the diet or to faulty absorption owing to the formation of insoluble compounds of P in the intestine. It is difficult to prepare a diet entirely free from P, but a low-P diet retards growth, the bones are poorly calcified, and the general condition is unsatisfactory; in extreme cases, the animals die Dietary phosphorus deficiency is seldom observed in man, but it is frequently observed in cattle in certain districts of South Africa or South America in which the soil and pastures have little phosphate. The animals have softening of the bones, and they eat the bones of dead animals (osteophagia). In extreme cases they also devour any solid object, such as tins, cinders, and clothes. This "perverted appetite" ceases when the phosphate content of the diet is increased.

Blood phosphorus. Blood contains inorganic phosphate and three forms of phosphorus in organic compounds: (*a*) ethereal phosphorus (glycerophosphate, hexosephosphate, etc.), which amounts to 24 mg. per 100 cc. and is found almost exclusively in the blood cells; (*b*) lipid phosphorus (phospholipids), of which there is 13 mg. in the cells and plasma; (*c*) nucleic phosphorus (in nucleic acids), of which there is only a small quantity. Total organic blood phosphorus amounts to 40 mg. per 100 cc.

There is approximately 3 to 4.5 mg. per cent inorganic phosphate in blood plasma of adults and 4 to 6 mg. per cent in children. It is diffusible phosphate and is found in the same concentration in blood plasma as in tissue fluids.

Hypophosphatemia is observed in (*a*) rickets due to vitamin D deficiency (inorganic phosphate is diminished); (*b*) osteomalacia, in which the bones soften, especially those of the pelvis (the disease is more frequent in women than in men); (*c*) hyperparathyroidism, in which there is also hypercalcemia and an increase in P excreted in the urine (in the advanced stages of the disease there are lesions in the kidney, P is retained, and the blood P may reach a normal or even a higher than normal level); (*d*) deficient absorption of P, owing to the formation of insoluble P com-

pounds in the intestine (rickets due to beryllium, strontium, etc.), or to disturbances in the intestinal mucosa (steatorrhea, celiac disease). The absorption of large quantities of glucose and insulin hypoglycemia cause a decrease in blood phosphorus, because hexosephosphate is formed and taken up by the tissues at a rapid rate.

Hyperphosphatemia is observed (*a*) when large doses of vitamin D or dihydrotachysterol are given, owing to mobilization of P stored in the bones (these substances also increase blood phosphates in hypophosphatemia of rickets); (*b*) in parathyroid insufficiency; (*c*) in severe diabetes; (*d*) in chronic renal disease, when plasma phosphate can rise to 8 mg. per cent and in extreme cases to 40 mg. per cent, as a result of retention of P (sometimes calcium phosphate is deposited in the soft tissues); (*e*) immediately after a bone is fractured, when blood phosphate usually increases for a short time.

Phosphatases. Enzymes that accelerate hydrolysis of monophosphoric esters, releasing phosphoric acid, are known as phosphatases.[1] They are found in nearly all the cells and tissue fluids. There are two phosphatases in blood plasma. One exerts maximum activity at pH 9; this is called alkaline phosphatase. There are large quantities of alkaline phosphatase in the intestine (absorption), kidney (excretion), liver (formation of phosphate compounds), and bones and teeth (ossification). The principal source of alkaline phosphatase appears to be the skeleton. It is increased in the blood in cases of rickets and other bone diseases (*e.g.*, Paget's disease), and less markedly in hyperparathyroidism, jaundice, and other disturbances of the liver, etc.

Acid phosphatase has its maximum activity in an acid medium. It is found in the liver, kidney, erythrocytes, etc. It is found in large quantities in the prostate, and in cases of cancer of the prostate it increases in the blood.

BONE AND THE FORMATION OF BONE

Composition. Bone in the body is a living tissue, made up of an organic matrix (30 per cent) impregnated with inorganic salts (45 per cent) and containing 25 per cent water. The inorganic salts in bone can be dissolved and removed by treatment with acid; the organic matrix that remains is elastic and flexible. This matrix is formed chiefly by a collagenous protein, called ossein. Calcination of bone destroys the organic matrix, and there remains a brittle structure (bone ash) which represents 45 per cent of fresh bone and 60 per cent of dried. This ash contains 37 per cent of calcium, 17 per cent of phosphorus, 0.5 per cent of magnesium, and small quantities of potassium, sodium, iron, chloride, and fluoride; the calcium-phosphorus ratio is 2:1. Calcium phosphate makes up about 85 per cent of the inorganic constituents of the bone, and calcium carbonate 12 per cent. The study of the crystalline structure of bone by means of x-ray diffraction has shown it to consist largely of a substance similar to apatite or hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$.

Functions of bone. The skeleton is the supporting framework of the body. It owes its rigidity to its mineral salts, and its elasticity to the organic matrix. When bone loses its minerals (decalcification) it loses its rigidity, softens, and is bent (rickets, osteomalacia, hyperparathyroidism). When the proportion of the organic components diminishes, bone becomes brittle and fractures easily (marble or chalky bone, or Albers-Schönberg disease).

There is active interchange of calcium and phosphate between bone tissue and the tissue fluids and plasma. When radioactive phosphorus (P^{35}) is administered, it is found in the bones after a few hours. Phosphorus and calcium stored in the bones are mobilized whenever there is deficiency of Ca. Thus when the diet does not contain a sufficient amount of Ca the blood Ca level does not fall; it is maintained by removing Ca from the bones, which are gradually decalcified (osteoporosis). Marked decalcification is also provoked by excess parathyroid hormone. Faulty deposition of Ca in bones is observed when there is vitamin D deficiency (rickets), and in thyroid and anterior hypophyseal insufficiencies.

Other elements besides Ca and P are deposited in the bone, *e.g.*, lead, radium, arsenic, and fluorine. If one of these substances stored in the bone (*e.g.*, lead) is suddenly mobilized, toxic symptoms (*e.g.*, lead poisoning) may be produced. For this reason a detoxicating function has been attributed to bone tissue. Substances

[1] Kay, H. D., *Physiol. Rev.*, **12**, 384, 1932; Bodansky, A., *J. Biol. Chem.*, **101**, 93, 1933; **104**, 473, 1934; Sunderman, F. W., *Am. J. Clin. Path*, **12**, 404, 1942; Jaffe, H. L., and A. Bodansky, *Bull. New York Acad. Med.*, **19**, 831, 1943.

stored in the bone can, nevertheless, produce harmful effects. Thus radium deposited in bones destroys the hemopoietic tissue in the bone marrow and may cause fatal aplastic anemia. An excess of fluoride in the bones alters their structure; they become hard and brittle (osteopetrosis) and bony excrescences (exostoses) are formed, but in some cases there are also decalcified areas and cysts.[1]

Ossification. Bone is formed from cartilage (endochondral ossification), or by the osteogenic cells under the periosteum (periosteal ossification). As soon as bone is formed it undergoes a process of reabsorption and replacement, which is very active in the fetus and child but diminishes as age advances. Bone increases in thickness as new layers are laid down under the periosteum; simultaneously bone is reabsorbed, and the central medullary canal is enlarged to such an extent that the femur of a fetus can be introduced into the central canal of an adult's femur. This process can be demonstrated by adding alizarin to the food. The dye is deposited in newly formed bone and gives it a red color. The new red layer is found under the periosteum if the bone is examined soon after the dye has been given. As time passes, it is displaced toward the central cavity by the more recent layers, until it forms the innermost layer around the central canal and is finally reabsorbed.

Growth in length is achieved by ossification of the epiphyseal cartilage (endochondral ossification). Cartilage cells proliferate and are disposed in columns; later they become swollen and vacuolized. Calcium salts are deposited in the organic matrix that surrounds these cells. Blood vessels and cells from the bone marrow then penetrate the ossifying cartilage, and the final structure of bone is completed. Endochondral ossification cannot proceed normally if there is deficiency in vitamin D or phosphorus, as in rickets. The cartilage cells continue to proliferate, the epiphyseal cartilage widens, and the cell columns become irregular, but little calcium is deposited in the osteoid layer, and ossification is not completed. In thyroid and hypophyseal insufficiencies the development of the cartilage cells and ulterior ossification are retarded. In normal subjects ossification is complete and the epiphyseal plate is closed at the age of twenty or twenty-five years. In castrates epiphyseal endochondral ossification continues for several years more; for this reason their limbs are abnormally long. Excess secretion of anterior hypophyseal growth hormone provokes hypertrophy and hyperplasia of the cartilage cells and causes giantism or acromegaly.

Parathyroid hormone regulates the reabsorption of bone. An excess of this hormone produces decalcification of bone and the disease known as osteitis fibrosa cystica.

The process by which crystallized calcium phosphate is deposited in the bones is not yet completely known. An organic matrix is formed, and then Ca phosphate is deposited; later the crystal is formed by the addition of Ca ions, hydroxyl, and calcium carbonate. Finally most of the calcium is in crystals similar to apatite (carbonate apatite).

Saturation and precipitation in a calcium phosphate solution are determined not by the total amounts of calcium and phosphate, but by the product of the concentration of calcium and phosphate ions, *i.e.*, $[Ca^{++}] \times [PO_4^{\equiv}]$. The ion product at which the solution is just saturated is known as the "solubility product." In blood plasma part of the Ca is bound in Ca proteinate, which is a weak electrolyte and therefore has a low degree of dissociation. Plasma thus dissolves more calcium than is dissolved in distilled water. CO_2 also increases calcium solubility. A decrease in plasma protein or in CO_2 diminishes the solubility of calcium which tends to precipitate. Phosphate concentration in plasma seems to be of greater importance than the solubility product for the process of bone formation, because the administration of phosphate is more efficacious than that of Ca in the treatment of rickets in which plasma-phosphate concentration is below normal.

According to Robison,[1] phosphatase plays an important part in ossification. This enzyme disintegrates monophosphate esters (hexosephosphate, glycerophosphate) and releases PO_4 ion, thus increasing the ion product $[Ca^{++}] \times [PO_4^{\equiv}]$ locally where it acts, *e.g.*, in bone cartilage. When the ion product exceeds the solubility product, *i.e.*, the solution is supersaturated, calcium phosphate precipitates and is deposited in

[1] A certain amount of fluorine strengthens the dentine in teeth, and increases the resistance to caries, but a larger percentage of fluorine in the teeth "mottles" the enamel. Large doses of fluorine cause disturbances in bones and teeth (see "Fluorine," page 491).

[1] Robison, R., and K. M. Soames, *Biochem. J.*, **18**, 740, 1924.

the organic matrix of bone cartilage. The following facts support this theory: (*a*) phosphatase is in high concentration in bones and teeth, especially in the epiphyseal cartilage when active calcification is taking place, but there is none in resting or nonossifying cartilage, such as that on the surface of joints; (*b*) rachitic bones contain phosphatase, so when they are submerged in a solution of calcium hexosemonophosphate, calcium phosphate precipitates. Certain facts, however, are not explained by this theory; thus, there are tissues which do not ossify but in which there are large quantities of phosphate. Moreover there is very little hexosemonophosphate in tissue fluids. Robison has postulated the existence of two different mechanisms that take part in ossification. One is the phosphatase mechanism; the other is not yet well known but is inhibited by cyanide.

The organic matrix seems to contain a factor of ossification that is resistant to heat, because a piece of boiled bone cartilage ossifies if it is placed in the peritoneal cavity, although its cells and enzymes have been destroyed, also, bone is formed if an alcoholic extract of epiphyseal cartilage is injected into a muscle.[1]

The formation of bone is the result of an equilibrium between local processes and the composition of plasma and tissue fluids, which regulates the continuous deposition of calcium salts in the bones and their reabsorption. The following factors are known to play a part in this process: (*a*) the balance between the calcium intake and excretion; (*b*) vitamin D; (*c*) plasma calcium and phosphate concentration; (*d*) hormones secreted by the parathyroid, anterior hypophysis, thyroid, and gonads; (*e*) vitamin C, which has some influence on the vitality of osteoblasts and odontoblasts; (*f*) accidental factors, such as fluoride and perhaps others still unknown, which regulate the formation of ossein.

IRON METABOLISM

Functions and distribution. Iron is essential for life. It is necessary for the formation of erythrocytes (hemopoiesis). It forms part of respiratory mechanisms such as blood hemoglobin, myohemoglobin, and cytochromes. There is 5 gm. of iron in the body; 65 per cent is in hemoglobin; 15 per cent in the liver, spleen, and bone marrow; and 20 per cent in other tissues. Hemoglobin has 0.34 per cent iron; therefore in 100 cc. of blood there is 52 mg. of iron in man and 45 mg. in women. There is very little iron in blood plasma (0.08 to 0.12 mg. per cent).

Requirement. The minimum iron requirement is probably 5 mg. per day, but a normal diet should contain from 10 to 20 mg. daily. An adult man or woman should receive 12 mg.; a pregnant or lactating woman, 15 mg.; a child during the first year of life, 6 mg. The intake should rise from 7 to 10 mg. between the second and tenth year, and up to 12 mg. by the twelfth year.[1]

Relatively large quantities of iron are found in liver, meat, egg yolk, green vegetables, and legumes. Milk contains very little iron. If it is the sole food for a long time, the subject becomes anemic when the iron stores are exhausted. Human milk has more iron than cow's milk. Repeated hemorrhages, even if they are small, *e.g.*, intestinal hemorrhage caused by hookworm, provoke anemia due to iron deficiency; a meat diet or iron treatment (O. Cruz) prevents or cures this type of anemia. Anemia due to iron deficiency is of the microcytic hypochromic type; it is more frequent in women and children than in men. Total deprivation of iron has been observed only in laboratory experiments. It is fatal if sufficiently prolonged.

Iron is absorbed in the duodenum, probably as a ferrous salt; after it is absorbed it is carried in the plasma as a ferric salt. Experiments with radioactive iron, which has a half life of 47 days, have shown that iron absorption is regulated by a mechanism in the intestinal mucosa, so that the intake is adjusted to the needs of the organism. Normally very little iron is absorbed, but as soon as the store of iron in the body diminishes, the amount absorbed increases.[2] The acidity of the gastric juice is an important factor in iron absorption, which diminishes when there is anachlorhydria. Iron absorption diminishes when substances are ingested that form insoluble iron salts, *e.g.*, phytic acid, brown bread, etc. In wartime, when there is a large consumption of brown bread, iron should be added to the flour.

Iron is eliminated by the cecum and the large

[1] LEVANDER, G., *et al.*, *Nature*, **155**, 148, 1945; **157**, 587, 1946.

[2] HAHN, *et al.*, *J. Exper. Med.*, **69**, 739, 1939; **78**, 169, 1943.

intestine. Most of the iron in the feces comes from food that has not been absorbed; only a small part is iron excreted from the body, because although hemoglobin is being continuously destroyed, its iron is retained and used in the formation of new hemoglobin.

A crystallized protein, called "ferritin," has been obtained from the liver and spleen; it has 20 per cent iron.[1] It apparently plays a part in intestinal absorption and in storage of iron. It has an antidiuretic effect and seems to be the vasodepressor substance released by the liver during shock (Mazur and Shorr). It controls the passage of iron through the intestine, kidney, and placenta. It combines with a protein (transferrin) which carries iron in the blood plasma.

The following disturbances in iron metabolism may be mentioned: (*a*) there may be hypochromic anemia due to dietary iron deficiency; (*b*) in hemosiderosis a brown pigment called hemosiderin, containing iron, accumulates in the reticuloendothelial system; (*c*) after splenectomy iron is not stored as efficiently as in normal subjects, and the excretion of iron increases, resulting in an iron deficiency which may cause anemia.

OTHER MINERAL CONSTITUENTS

Magnesium. This is an essential element in several enzymatic systems, such as those of phosphorylase, carboxylase, and cozymase. In plants it is found in chlorophyll and is comparable to iron in hemoglobin. Rats fed on a diet completely free from magnesium suffer from convulsions and tetany and eventually die.[2] Magnesium deficiency provokes tetany in cows that have recently calved and in lactating cows. The condition is cured by the ingestion of Mg or Ca. The minimum daily requirement of magnesium is 0.22 gm.,[3] but a normal diet should contain 0.27 gm. (Sherman).

Magnesium is absorbed in the small intestine. Phytates in cereals form insoluble Mg compounds and decrease its absorption. Magnesium is excreted mainly in the feces (50 to 80 per cent). Blood plasma has a Mg concentration of 1.8 to 3.6 (average 2.5) mg. per cent, and erythrocytes 5.4 to 7.8 mg. per cent. When the concentration in plasma rises to 5 mg. per cent, there is somnolence. Lethargy increases and the subjects become comatose as the concentration rises to 15 and 20 mg. per cent. Intravenous injection of Ca diminishes the toxic effects of magnesium.

Iodine. The daily requirement is between 100 to 200 μg (2 to 4 μg per kg.). In districts where endemic goiter is prevalent these quantities should be doubled. Iodine metabolism will be fully considered in Chap. 53, The Thyroid Gland.

Fluorine. Very small amounts of fluorine are found in the bones and teeth. If the drinking water contains 1 to 2 mg. F per liter, white patches appear on the surface of the teeth, and brown or black patches if there is 2.5 mg. or more per liter. This is due to a disturbance in the structure of enamel, which becomes porous and pigmented (mottled enamel). Sensitiveness to fluorine varies from one individual to another, but if there is 5 to 6 mg. per liter of F in the drinking water, 100 per cent of the population have mottled enamel. The structural change in the teeth takes place in infancy when the teeth are developing. If drinking water contains 1 to 1.5 mg./liter, the incidence of caries diminishes and the resistance of dentine increases. Cases of osteopetrosis (compact "marble" bone) have been reported in districts in which there is a high concentration of F in drinking water (*e.g.*, La Pampa, Argentina). Most of the patients were over thirty years old. Large doses given experimentally to rats produce severe lesions in bones and teeth. The bone is compact and petrous in patches, while in other parts there may be osteoporosis, cyst formation, or bony excrescences (osteophytes).

Zinc. Zn is apparently an indispensable element. It forms part of the carbonic anhydrase enzymatic system; it has been found in crystallized insulin and in some snake venoms. It is taken up mainly by the liver and pancreas and is excreted principally in the pancreatic juice.

Cobalt. This metal is indispensable in animal nutrition. Cobalt has been found in vitamin B_{12}. Pancreatic tissue contains cobalt and nickel (Bertrand). Cobalt deficiency has been reported in certain districts of Scotland and New Zealand, in which diseases and mortality in sheep due to this deficiency have been observed.

[3] Tibbets, D. M., and J. C. Aub, *J. Clin. Investigation*, **16,** 491, 1937.

Other elements. Manganese is indispensable to rats and chicks; it forms part of several enzymatic systems. It is eliminated mainly in the bile. Copper reinforces the effect of iron in the formation of erythrocytes and hemoglobin in rats kept on a exclusively milk diet. This effect has not been observed in man. Deficiency of Cu has never been reported; apparently the small amount of Cu in food and water is sufficient for the needs of human nutrition, which have been estimated to be 50 μg per kg. daily.

Toxic effects. Minerals sometimes produce toxic effects. Fluorine intoxication has been observed in districts with a high F content in the drinking water and near aluminum factories where F expelled in smoke is condensed by fog. Chronic intoxication by arsenic has been reported to be endemic in certain districts (Córdoba, Argentina); it produces pigmentation of the skin, hyperkeratosis, and several visceral disturbances (Ayerza). Intoxication of cattle by selenium, molybdenum, lead, or fluorine in water or pastures has been reported. This contrasts with diseases due to deficiency of some element, such as those caused by Ca, Mg, P, or Co deficiency. Intoxication or diseases in workers due to industrial utilization of minerals are fully considered in treatises on industrial hygiene.

CHAPTER 46

Metabolism in Fasting, Malnutrition, and Obesity

METABOLISM IN FASTING

During a complete fast, the body functions at the expense of substances stored and taken from the tissues. Carbohydrate stores amount to a few hundred grams and are depleted in one or two days; energy is thereafter obtained mainly (80 to 90 per cent) from fat and in a lesser degree (10 to 20 per cent) from protein. In an advanced stage, when all storage fat has been burned, there is a profound change in metabolism and large quantities of protein are consumed.

Glycogen stores diminish rapidly, but even after a long fast there is glycogen in the heart and muscles and a small amount in the liver, which is formed by glyconeogenesis. The blood sugar falls a little, but it is maintained within the normal range. After a few days of fasting the capacity to utilize carbohydrate diminishes. Thus if glucose or carbohydrate is administered the rise in blood sugar is more marked and prolonged than in normal subjects; there is little or no increase in the respiratory quotient, and glycosuria is easily produced.[1]

Storage fat is the principal source of energy in fasting (Terroine's "élément variable," Chap. 42). If the fast is sufficiently prolonged 97 per cent is consumed (Voit). Tissue fat, mainly phospholipids (Terroine's "élément constant"), does not diminish much. Mobilization of storage fat causes a rise in lipemia and liver fat. The considerable increase in fat consumption leads to the production of large quantities of acetoacetic and β-hydroxybutyric acids in excess of that which can be oxidized by the organism. These acids are accumulated in the blood and excreted in the urine. Ketosis (*i.e.*, increased production and elimination of ketone bodies) causes acidosis, ketonuria, increased urinary ammonia, diminished alkali reserve, hyperventilation, and a low alveolar CO_2 tension.

Protein catabolism diminishes rapidly in the first two or three days of fasting, and therefore so does the excretion of nitrogen, sulfur, and phosphorus in the urine; later it continues to diminish gradually. Normally fed subjects eliminate 12 to 16 gm. of N daily; in subjects who had fasted for 31 to 38 days, the daily N elimination dropped to between 6.9 and 3.3 gm. The total amount of urine also decreased. Urea was the principal nitrogenous substance in the urine of these subjects; therefore urea is not only exogenous but also endogenous, *i.e.*, it is an end product of the catabolism of tissue protein. As the subjects lost weight creatinine excretion diminished, and creatine was found in the urine. Amino-acid concentration in plasma is not diminished in fasting subjects; therefore intestinal absorption is not the only source of the amino acids in the blood.

Feces are eliminated even when no food is taken. Succi, a subject studied by Luciani, continued to eliminate 9.5 to 22 gm. of feces with 0.3 to 1 gm. of nitrogen daily.

After the fat stores have been depleted, large quantities of protein are burned. Urinary nitrogen rises, and if the subject is not fed he dies. At this stage the capacity to burn carbohydrate improves; the administration of glucose is followed by a rise in the RQ (Hédon), not only in

[1] Claude Bernard first described these effects of fasting. Hofmeister (1890) gave the name of "hunger diabetes" to this condition. CHAMBERS, W. H., Undernutrition and Carbohydrate Metabolism, *Physiol. Rev.*, **18**, 248, 1938; LUNDBAEK, K., *Yale J. Biol. & Med.*, **20**, 533, 1948.

normal animals but also in diabetic ones, and the latter retain part of the glucose without excreting it into the urine (Chambers).

The mineral content of plasma is not changed, because the body retains salts, and the excretion of Cl, Na, K, and Ca diminishes. In the first stages NaCl is lost, together with extracellular water, but later NaCl excretion is reduced to a minimum. The loss of intracellular water is accompanied by the loss of potassium.

Table 59. Percentage of Weight Lost by Tissues during Starvation

Tissue	*Loss of fresh tissue, %*	*Loss of dry tissue, %*

Brain and spinal cord	3	0

Source: according to Voit.

The BMR decreases gradually; in some cases it falls by 30 and even 50 per cent. Body temperature, especially skin temperature, also drops a little. The pulse rate diminishes and intestinal absorption is slowed down. During the first days of fasting, intense hunger is felt, which diminishes later and is no longer felt after the first week. There is progressive weakness, leading to physical and mental lethargy and finally to coma and death. Occasionally hypoglycemic convulsions are observed.

Complete fasting leads to death after a time that varies in different species. Smaller animals with a higher BMR die sooner than larger animals with a low BMR. Professional fasters, such as Succi and Cetti, have fasted for 30 and even 50 days, drinking only water during that time. MacSwiney, the mayor of Cork, who refused food when imprisoned, died in coma after 74 days. A dog has been kept fasting for 117 days, without dying, in spite of having lost 63 per cent of its body weight. This is the longest period of fasting recorded in a homoiothermic animal. Poikilothermic animals survive many months of complete fasting if the environmental temperature is kept low.

Body weight is lost gradually and continuously during fasting. The decrease varies between 20 and 60 per cent, but is usually 40 to 50 per cent before the animal dies. Weight lost by the different tissues varies considerably (Table 59). Adipose tissue is almost completely lost, and about one-third of the muscle tissue is consumed.

* Previous day, 27.08.

† Previous day, 698.

The spleen, liver, and testes are particularly sensitive to fasting. On the other hand the heart and central nervous system lose very little weight. Some of the bodily changes observed in a subject who fasted for 31 days are given in Table 60.[1]

[1] The older literature on fasting is well summarized by E. Bardier in Richet, "Dictionnaire de physiologie," **9**, 58, Librairie Félix Alcan, Paris, 1913, and by G. Lusk (The Physiological Effects of Undernutrition, *Physiol. Rev.*, **1**, 523, 1921).

MALNUTRITION

Malnutrition occurs when the diet is deficient in one or more of its essential components, *i.e.*, calories, protein, certain amino acids, certain fatty acids, vitamins, or minerals. Deficiency in water or oxygen can also produce conditions similar to those of malnutrition. Complete absence of an essential constituent may frequently occur in times of war or famine, but partial deficiencies sometimes remain hidden and cause widespread damage. Production, transport, and distribution of food have improved continuously since the eighteenth century, and in more recent years the knowledge of nutrition has progressed considerably, so that generally speaking human beings are now better fed than ever before. On the other hand, war has created conditions of famine in certain populations such as have never been seen on so wide a scale.

Table 61. Effects of Malnutrition Due to Dietary Deficiency, Increased Metabolism, or Deficient Absorption

Cause of malnutrition	*Effects*
Deficiency in	
Calories	Loss of weight, weakness
Protein	Hypoproteinemia, edema, microcytic anemia, muscular wasting
Vitamin A	Keratosis in conjunctiva and mucosae; night blindness
Vitamin B_1 (thiamine)	Mental and physical fatigue, anorexia, polyneuritis, muscular cramps and pains, cardiac dilatation
Nicotinic amide	Pellagra
Riboflavin (vitamin B_2)	Weakness, cheilosis, stomatitis, nasolabial seborrhea, interstitial keratitis
Vitamin B complex	Deficiency in one of the vitamins is usually accompanied by some degree of deficiency in the other vitamins of the complex
Ascorbic acid (vitamin C)	Scurvy, capillary fragility
Vitamin D	Rickets
Tocopherol (vitamin E)	Sterility in rats (not proved in man)
Vitamin K	Prolonged blood-clotting time, diminished prothrombin
Calcium	Rickets in children; osteoporosis and osteomalacia in adults, especially in multiparous and lactating women
Iodine	Endemic goiter
Iron	Hypochromic anemia, especially in children and pregnant women and after repeated hemorrhage. Hookworm anemia
Chronic starvation	The effects of several deficiencies are observed
Increase in metabolism owing to	
Growth	Rickets, osteoporosis, anemia, retarded growth
Pregnancy, lactation	Child: rickets, anemia, retarded growth Mother: anemia, osteoporosis, weakness
Thyrotoxicosis, fever, leukemia	Loss of weight if additional calories to cover increased metabolism are not taken
Deficient absorption due to	
Deficiency in gastric acidity	Disturbances in bone
Deficiency in pancreatic lipase owing to (1) insufficient production (chronic pancreatitis) (2) obstruction of duct	Insufficient absorption of fat and vitamin A; steatorrhea; chronic undernutrition
Chronic diarrhea	Loss of fat, protein, vitamins, Ca, Fe; anemia, osteoporosis, tetany, edema, polyneuritis, pellagra, undernutrition

Source: after Newburg, with modifications.

Malnutrition may be caused by (*a*) insufficient ingestion of food; (*b*) deficient absorption of food; (*c*) increase in metabolism. Insufficient ingestion of food is frequently due to anorexia (lack of appetite), to food fads that cause the exclusion of an essential component or its reduction to quantities below the safety level, or to limitation of the diet to a few chosen foods, *e.g.*, white bread, sugar, and margarine. A frequent

cause of malnutrition in children and pregnant or nursing women, in many regions, is the scarcity of milk and milk products. Deficiencies in Ca, vitamin D, animal protein, vitamin B complex, and vitamin C are among those most commonly observed. Table 61 gives a summary of the outstanding symptoms typical of the most frequently found deficiencies.[1]

The signs and symptoms of malnutrition are similar to those of starvation. They have been observed in countries at war, in times of famine, in concentration camps, and also in experimental studies made on volunteers.[2] There is loss of weight and storage fat, which may be masked by edema. The subjects may become extraordinarily thin. The BMR falls 15 to 32 per cent and the body temperature diminishes slightly (0.5 to 0.9°C.). There is bradycardia, the heart is smaller, and the blood pressure decreases (about 20 per cent). The erythrocytes and hemoglobin are slightly below normal. The subjects are physically weak and mentally exhausted; they are apathetic and apparently lazy. Susceptibility to infections increases. Acidosis occurs frequently, especially in fat subjects, but it is usually well tolerated. Intense and prolonged undernourishment may cause hypophyseal and sexual functions to diminish.

In certain forms of malnutrition prevalent in parts of Africa and Central and South America, there is a high infantile morbidity and mortality. Children suffering the disease known in Africa as *kwashiorkor* (red child), due mainly to protein deficiency,[3] have red or straw-colored hair, staining or thickening of the skin, edema, anemia, gastrointestinal disturbances, and fatty degeneration or cirrhosis of the liver; the mortality is high (Gillman).

A well-balanced and plentiful diet improves growth, raises the average height, and increases the average life span of any population.[4]

[4] In countries where food is plentiful, such as the United States and Argentina, the offspring of European immigrants are on an average taller than their parents, who were brought up in a less well-fed community Mendel obtained an increase in size in white rats by improving the diet.

OBESITY

Obesity is an important problem in nutrition and preventive medicine. More than one-fifth of the adults in well-fed countries are obese. Degenerative diseases are more frequently observed in fat than in thin persons; also the average life is shorter in fat people.

Usually 15 to 17 per cent of the body weight is fat, but this varies considerably in different individuals. The fat content can be determined in living subjects by (*a*) measuring the body water (McCance and Widdowson); (*b*) measuring the specific weight of the body (Behnke), since fat is less heavy, having a specific weight of 0.92; (*c*) measuring the thickness of skin and subcutaneous folds; (*d*) anthropometric measurements and x-rays.

Obesity is sometimes classified, according to the mechanism of its production, into (*a*) alimentary or exogenous obesity, due to excessive food intake; (*b*) constitutional or endogenous obesity, attributed to the hereditary constitution of the subject; (*c*) endocrine obesity, which may be due to disturbances in the functions of the hypophysis (dystrophia adiposogenitalis; Cushing's disease), adrenals (hypercorticalism), thyroid (hypothyroidism), or gonads (menopause; castration); (*d*) obesity due to brain lesions, especially those of the hypothalamus. The diet is a fundamental factor in all forms of obesity, since fat stored has its origin in food. Obesity diminishes when food is restricted; there were no obese persons in Europe at the end of the Second World War. Other factors contribute to increase fat storage by different mechanisms. Endocrine factors will be considered in the chapters on the respective glands. Obesity due to brain lesions is usually preceded by an increase in appetite (hyperphagia); this has been observed in animals with lesions in the hypothalamus[1] and after removing the frontal lobe.[2]

The metabolism of obese subjects has been carefully studied.[3] Usually there is no abnormality in the BMR. The specific dynamic effect is normal or slightly below normal, but this decrease does not cause the total metabolism to

[1] HETHERINGTON, A. W., and S. W. RANSON, *Am. J. Physiol.*, **136**, 609, 1942; BROBECK, I. R., *et al.*, *Yale J Biol. & Med.*, **15**, 831, 855, and 893, 1943.

[2] BEACH, F. A., *J. Comb. Psychol.*, **31**, 145, 1941.

[3] EVANS, F. A., in Duncan, "Diseases of Metabolism," Saunders, Philadelphia, 1947; NEWBURGH L. J., and J. W. CONN, *Physiol. Rev.*, **24**, 18, 1944.

fall by more than 3 per cent. Nitrogen metabolism is normal and nitrogen equilibrium is maintained with 1 gm. of protein per kg. daily even if the total caloric intake is reduced to 400 kg.-cal. Creatinine excretion is proportional to the muscular development of the subject; the daily elimination per kilogram of total body weight is below normal.

Familial factors play a part in some cases of obesity, *e.g.*, a constitutional deviation in metabolism. For instance, lipophilia, *i.e.*, abnormally high formation and storage with low utilization of fat, is often supposed to be a cause of obesity, but this has never been satisfactorily demonstrated. Familial customs, such as overeating and sedentary habits, are frequently the cause of obesity.

Endocrine disturbances are a factor in some forms of obesity, but not in all, as is frequently mistakenly supposed. In hyperthyroidism the increased metabolic rate causes loss of weight and the patients are usually thin, but although obesity is observed in some cases of hypothyroidism, all obese subjects do not suffer from thyroid insufficiency. The mechanism of obesity in Cushing's hypophyseal basophilism and in hypercorticalism is not known. Hypophysectomized rats eat little, lose weight, and frequently become cachectic; forcibly fed by a stomach tube, they store more fat than normal controls on the same diet.[1]

Obesity increases the demand on the heart and circulation. The percentage of persons with high blood pressure is higher among the obese than among those with normal weight. Obesity frequently precedes diabetes. Subcutaneous fat hinders the loss of heat by irradiation, and for this reason obese subjects perspire more than thin ones. The average life of obese persons is shorter than that of thin ones and those of normal weight; hence the saying that "as the waistline lengthens the life line shortens."

Treatment of obesity consists mainly in the reduction of the food intake. Exercise may help by increasing the consumption of storage fat, but it should be prescribed in moderation; otherwise it may be harmful. Hundreds of "reducing systems" have been proposed; some are inefficient, and others are dangerous because they restrict the intake of essential foods. A normal adult weighing 130 to 150 lb. who develops moderate physical activity needs 2500 kg.-cal. daily. An obese person must reduce this to 1000 or 1200 kg.-cal. daily to lose weight; occasionally, and only for a short period, the daily caloric intake may be reduced to 600 or 400 kg.-cal. Care should be taken that essential foods such as vitamins, salts, and adequate protein are given. It must be remembered that to lose 1 kg. of fat the equivalent of 7000 cal. must be burned. The most difficult obstacle to overcome in the treatment of obesity is a large appetite. This is easily controlled for a short time, during which weight is lost, but often this control breaks down and fat is again stored.

CHAPTER 47

The Physiology of Physical Exercise

THE TERM "PHYSICAL EXERCISE" is usually restricted to the mechanical phenomena accompanying the activity of the organs of locomotion, but efficiency in exercise demands the correlated cooperation of all the organs and systems in the body. In studying the physiology of physical exercise it is therefore necessary to consider the organism as a whole made up of integrated parts, the actions of which combine with admirable precision.

The knowledge of the physiology of exercise has many applications. In the first place, work is often a form of exercise. The social importance of work has stimulated the study of this aspect of physiology to such an extent that industrial physiology is now a well-recognized specialty. In the second place, we are living in a mechanical age, and this has created sedentary habits which have made physical exercise necessary for the maintenance of health. To be of benefit, physical exercise must be adapted to the capacity of the individual who practices it. Lastly, an important factor for national defense is the rapid preparation of large forces of men with a high standard of physical efficiency. All the effects of exercise on the different systems and the demands it makes on the organism must therefore be well understood. In this chapter the results of training and the efficiency of the organism as a machine that transforms energy will also be considered, together with other problems of industrial and aviation physiology.

The greater part of the results to be discussed have been obtained from observations and experiments made on man.

OXYGEN CONSUMPTION

Physical examination of a subject who has run a hundred yards shows "shortness of breath," *i.e.*, increased frequency (polypnea), together with some difficulty in breathing (dyspnea). A vigorous rapid heartbeat can be felt by palpating the thorax, and the pulse is more frequent. There are sweating, vasodilatation of the skin, and a rise in body temperature. These are signs of an increased metabolic rate. Muscular contraction is accompanied by an increase in oxygen consumption because, when working, the muscles require a supplement of energy, which is obtained by burning a larger amount of foodstuffs. This increase in combustion causes an increase in the oxygen consumption of the whole organism, and several adjustments in the respiratory and circulatory functions must be made

Table 62. Bodily Changes Produced by Exercise

	Resting	*During exercise*	
		Average	*Maximal*
Oxygen consumption, cc. per min	250	2,500–3,500	5,000
Oxygen debt, liters	....	4–8	16–19
Lactacidemia, mg. per 100 cc. blood	15	50–100	200
Respiration			
Rate	12–16	30	60
Inspiratory volume, cc.	350	2,000	2,200
Ventilation, liters per min.	4.5–6	50–70	120
Circulation			
Pulse rate	70	120–150	200

Minute volume, liters	4–5	10–20	35
Systolic arterial blood pressure, mm. Hg	120	160	180
Temperature Δ °C.	....	0.5–1	2

to assure the arrival of more oxygen to the active muscles (Table 62; Fig. 208).

The rate of oxygen consumption in man during exercise increases proportionally to the work performed and can be as much as 10 and 20 times the basal rate. Table 63 summarizes Benedict and Murschhauser's observations in moderate exercise.
FIG. 208. Oxygen consumption and work performed. In this case work was measured by the revolutions per minute ot a bicycle wheel with loads of 1.5 and 0.5 amp. (*From Benedict and Cathcart, Carnegie Institution, Pub. No. 187, Washington, D.C., 1913.*)

Table 63. Oxygen Consumption and Energy Output in Different Conditions

Condition	*Oxygen consumption, cc. per min.*	*Energy output*	
		Cal. per min.	*Cal. per m.*
Lying down	226–242	1.14	
Sitting	234–260	1.19	
Standing at ease	238–239	1.25	
Standing to attention	....	1.30	
Moving the arms	516	2.53	
Walking			
53 m. per min	667	3.4	0.064
112 m. per min	1296	6.7	0.053
146 m. per min	2240	11.5	0.077

Data taken from BENEDICT, F. G., and H. MURSCHHAUSER, "Energy Transformations during Horizontal Walking," Carnegie Institution, Pub. No. 231, Washington, D.C., 1915.

If the oxygen consumption is measured once a minute during and immediately after moderate exercise and the results are plotted against time, a curve like that of Fig. 209 results. At the beginning of exercise oxygen consumption increases progressively up to a maximum, at which it remains as long as the exercise lasts. When muscular activity comes to an end, the oxygen consumption decreases more or less rapidly, according to the intensity of the exercise performed, and returns to the basal level. The curve can be divided into three parts: (*a*) progressive increase in oxygen consumption; (*b*) steady state; (*c*) recovery.

During the first few minutes of exercise, while the oxygen consumption rises, the oxygen absorbed is less than that needed to oxidize the metabolic products of muscular contraction. This is due to the delay in the adaptation of the respiratory, and especially the circulatory, functions to the greater demand of oxygen by the tissues. Nevertheless the muscles continue to contract, in great part by means of the energy set free by anaerobic chemical reactions. The relative lack of oxygen prevents the complete resynthesis of the lactic acid produced into glycogen. This acid accumulates in the muscle and passes out into the blood; theretore lactacidemia increases. During the steady state a balance is established between the need of oxygen and the speed at which it is delivered to the muscles and used up by them. The amount of lactic acid accumulated neither increases nor diminishes. During recovery the rate of oxygen consumption should fall suddenly to the resting level, but it does not, because the lactic acid which is accumulated during the first stages and which is not removed during the steady state must be disposed of during the period of recovery. The organism has contracted an "oxygen debt," the payment of which is postponed until the exercise has ended. By "oxygen debt" is meant, therefore, the amount of oxygen, in liters, necessary for the removal of metabolic products accumulated while the supply of oxygen is below the needs of the organism. This debt is measured by the amount of oxygen consumed above the basal rate between the end of the exercise and the time when the oxygen consumption has fallen to the resting level.

In violent exercise the oxygen-consumption curve is different. It first increases to a maximum, which is higher than that of the steady state of moderate exercise, but nevertheless does not completely satisfy the oxygen requirements of the organism. The oxygen debt is much

greater and the recovery period more prolonged (Fig. 210).

The exercise an individual can perform is limited by the oxygen supply in one of two ways. In the first place, there is a maximum rate at which oxygen can be absorbed, transported, and used, determined by the efficiency of the respiratory and circulatory adaptations. This maximum is usually 4 liters per min., but in exceptional cases higher figures up to 5.35 liters have been recorded.[1] This maximum rate puts a limit to the speed of exercise; *e.g.*, in a 5,000-yd. race the athlete will have to run at a speed allowing the establishment of a steady state, in which oxygen consumption is sufficient to cover the demand.

In the second place, there is a limit to the oxygen debt that the organism can contract to be paid during the period of recovery. This put a limit to the time during which violent exercise can be performed. In a 100-yd. sprint the runner develops the maximum speed possible, and in the 11 to 12 sec. that the race lasts, only one-sixth of the oxygen necessary can be taken in. The greater part of the muscular effort is made on an oxygen debt, which will be paid during the period of recovery; the larger the maximum possible debt, the longer will the individual be able to sustain the effort. "Oxygen credit" varies from one individual to another. It is large in athletes and can be developed by training up to 16 to 19 liters of O_2 per minute.[1]

FIG. 209. Diagram of oxygen consumption before, during, and after moderate exercise. 1, period of progressive increase; 2, steady state; 3, recovery. Area *A* represents the oxygen needed above the oxygen consumption (oxygen debt). Area *B* represents the oxygen consumption above the actual need (payment of the oxygen debt). *A* and *B* cover the same surface.

FIG. 210. Oxygen need (striped area) and oxygen consumption (curve) in violent exercise.

The intensity of work or exercise can be measured by the rate of oxygen consumption. Dill has suggested a classification into three types of exercise: *moderate*, when the oxygen consumption is up to three times the basal rate; *heavy*, when it is three to eight times the basal rate; and *maximum*, when it is more than eight times the basal rate.

LACTACIDEMIA

When the oxygen demand is greater than the supply, *i.e.*, when there is an oxygen debt, as

[1] ROBINSON, S., H. T. EDWARDS, and D. B. DILL, *Science*, **85**, 409, 1937.

[1] SERGENT, R. M., *Proc. Roy. Soc., London, s.B.*, **100**, 10, 1926.

during the first stages of moderate or in maximum exercise, lactacidemia increases from a resting level of about 15 mg. per cent to 100 and even 200 mg. per cent.

The lactacidemia level represents an equilibrium between the production and removal of lactic acid. One source of lactic acid is its formation in the blood (by glycolysis), which increases in alkalosis and also when the blood passes through the lungs. Another and more important source is muscular contraction, during which glycogen is first broken down to lactic acid and then again resynthesized to glycogen when energy is provided by oxidation (the Pasteur-Mayerhof cycle).

When there is a strong or sustained muscular contraction, the insufficiency of the oxygen supply causes the accumulation of lactic acid, which diffuses into the blood stream. The lactic acid formed by glycolysis or in the course of muscular contraction can be excreted in the urine or sweat, or utilized by the heart, or reconverted into glycogen by the muscle, but the greater part of that which has passed into the blood is taken up by the liver and converted into glycogen (the Cori cycle). Oxygen is needed for this resynthesis.

When the formation of lactic acid does not exceed the capacity of the organism to remove it, as in the steady state of moderate exercise, lactacidemia does not increase. When the effort is greater, during the initial phase while the oxygen supply is below the demand, lactic acid will accumulate in the blood. It will remain at a fairly constant high level if a steady state is established. Later, during the period of recovery, lactacidemia will fall rapidly to the resting level. When the exercise is such that even the maximum possible absorption of oxygen falls short of the requirements, there is no steady state; lactic acid continues to accumulate until the exercise must be discontinued because of fatigue. In this case a maximum oxygen debt has been contracted, and there is a prolonged period of recovery.

There is an evident connection between the lactic-acid level in the blood and the oxygen debt (Fig. 211). At one time Hill believed that an oxygen debt always signified an increase in blood lactic acid and that the excess oxygen consumption of the recovery period was utilized in the removal of the excess lactic acid. It is now admitted that oxygen is used also for the removal of other substances accumulated in the course of muscular contraction. In light exercise there is an oxygen debt without any increase in lactacidemia.[1] It is possible that in this case small amounts of lactic acid or other metabolic products are accumulated in the muscle. Above a certain level of oxygen debt there is a lineal relation between it and lactacidemia (Fig. 211); therefore the capacity of the organism to contract an oxygen debt is related to its ability to limit or tolerate the increase in blood lactic acid.
Fig. 211. Lactacidemia and oxygen debt.

The increase in lactacidemia produces several effects:

1. Part of the excess lactic acid is excreted by the kidney. There is therefore an increase in lactic acid and ammonia in the urine collected during and after a period of exercise.
2. Lactic acid displaces CO_2 from the base with which it is combined and forms lactates. This results in an increased respiratory output of CO_2 (see below) and a fall in the alkali reserve.
3. The accumulation of lactic acid in the blood can increase the hydrogen ion concentration and thus stimulate the respiratory center, provoking hyperpnea which results in a speedier elimination of CO_2.

All these adjustments, especially those taking place in the initial period, result in the elimination of a larger amount of CO_2 than that corresponding to the consumption of oxygen, and thus the RQ increases and in some cases reaches values near 2. Respiratory distress (dyspnea) at the beginning of exercise has been attributed to the excess lactic acid. It disappears suddenly

[1] Owles, W. H., *J. Physiol.*, **69**, 214, 1930; Margaria, R., H. T. Edwards, and D. B. Dill, *Am. J. Physiol.*, **106**, 689, 1933.

("second wind") once the necessary adaptation has been accomplished, even though the effort is sustained at the same level. This disappearance of dyspnea is probably due to readjustments in respiratory and circulatory functions and in temperature regulation.
FIG. 212. Pulmonary ventilation and oxygen consumption while walking at different speeds. (*Drawn from Gemmill, "Physiology in Aviation," Charles C Thomas, Springfield, Ill., 1943.*)

RESPIRATORY CHANGES

A visible effect of exercise is the increase in the frequency and depth of breathing. The frequency can rise from 16 to 20 movements per minute in the resting state to 50 or more per minute in violent exercise, and the inspiratory volume can increase from 500 to 2,000 cc. An increased ventilation results, as a result of which the oxygen intake can increase. There is a direct relationship between pulmonary ventilation and work performed, and between pulmonary ventilation and oxygen consumption (Fig. 212).

The mechanism by which this perfect adjustment between oxygen consumption and pulmonary ventilation is carried out is as yet incompletely understood. In the course of physical exercise there are several changes in the chemical composition of the blood which can provoke hyperpnea. Thus, the rise in CO_2 tension, the fall in O_2 tension, and the decrease in pH are factors which stimulate the respiratory center and peripheral chemoreceptors.[1] Breathing air with an excess of CO_2 causes a result similar to that of exercise; first the depth and then the frequency of the respiratory movements increase. Nevertheless, by adding CO_2 to the inspired air it is not possible to provoke such an intense hyperventilation as can be obtained by violent exercise. Dripps and Comroe[1] observed on an average a respiratory volume of 76.3 liters per min. in normal subjects breathing oxygen with 10.4 per cent CO_2. The same subjects raised the respiratory volume to 109.6 liters per min. during maximum exercise. It has also been found that in some types of exercise the respiratory volume continues to increase although the alveolar CO_2 tension falls.

A certain relation between the pH of arterial blood and pulmonary ventilation has been found, although this relation is not a simple one.[2] Gesell[3] maintains that the regulation of the respiratory rate is mainly due to changes in the pH of the respiratory center. In moderate work, however, there is no change in the pH of the blood, and the oxygen tension does not fall.

An increase in the excitability of the respiratory center has been considered by some workers as the principal mechanism in the respiratory adaptation to exercise. The results of certain experiments are in favor of this interpretation; thus, adding 3 per cent CO_2 to the inspired air causes a much greater increase in ventilation during exercise than at rest.[4] The fact that the respiratory rate increases rapidly from the very beginning of exercise, before metabolic products can accumulate in the blood and act on the respiratory center, has been attributed to reflex stimulation of this center. These reflexes have their origin in the active muscles and joints,[5] in the lungs, in the carotid or aortic bodies, and in the great veins and auricles, or are due to substances produced by the muscles acting on chemoreceptors.[6] The excitability of the respiratory center could also be increased by changes in the circulation and therefore in the blood supply of the center,[7] or by the irradiation to the respiratory center[8] of impulses that go from the brain to the active muscles.

To sum up, nerve impulses arising in the active limbs and the lungs, or irradiated from the cortex to the respiratory center, play an important, but not exclusive, part in the hyperpnea of exercise. The increase in CO_2 and the decrease in pH in the blood, the accumulation of lactic acid, the changes in the circulation occurring in the respiratory center, impulses arising in the carotid and aortic bodies, and even the increase in body temperature, add their effects to those mentioned above and contribute to produce hyperpnea.[1]

CIRCULATORY CHANGES

Muscle performs work by burning fuel. Therefore when work increases, as in exercise, the oxygen supply must also be increased, hence a greater blood flow is needed through the active muscles. Krogh, Rein, Millikan, and others have demonstrated this increase in blood flow, which is prolonged beyond the period of activity. An exception to this occurs when there is a very strong and sustained contraction, in which case the blood flow diminishes or even ceases, but once the contraction is ended the blood flow is considerably increased.

This increase in blood flow is produced mainly by two mechanisms: (*a*) a local vasodilatation; (*b*) a rise in blood pressure. Local vasodilatation of arterioles and capillaries is always accompanied by the opening of a large number of capillaries that were closed in the resting muscle.[2] The number of open capillaries in an active muscle can be up to 10 times those open in a resting muscle. Thus oxygen pressure in the tissues is raised, and oxygen consumption by the muscle increases between 33 and 90 per cent.

There are nervous and humoral mechanisms of vasodilatation. The nervous mechanism consists in a diminished vasoconstrictor tone, produced reflexly by the action of the high blood pressure on the carotid sinus. The humoral mechanisms have local effects of great importance. During exercise the increased CO_2 tension, the decrease in O_2 tension and pH, the local accumulation of metabolic products such as lactic acid, adenylpyrophosphate, etc., cause local vasodilatation in the active muscles and thus increase the local blood flow.

[2] Krogh, A., "The Anatomy and Physiology of the Capillaries," revised ed., Yale University Press, New Haven, 1929.

There is usually an increase in the cardiac output.[1] The minute volume is 4 to 5 liters in the resting subject, but it can rise to 35 liters in violent exercise. This increase is proportional to the work performed per minute, and it is brought about by a faster heart rate and a greater systolic output. When the exercise ceases, the minute volume rapidly falls to the resting level.

Systolic output. The systolic output is 60 to 70 cc. in the resting normal subject, and it can increase to 100 to 150 cc. in maximum exercise performed by trained athletes. The systolic output is dependent on the amount of blood returning to the heart; therefore the venous return must increase during exercise. A complicated mechanism carries this out:

1. There is an increase in the circulating blood volume, produced by the evacuation of stored blood in the skin, splanchnic area, liver, spleen, etc.
2. The venous return is increased by (*a*) the contractions of the skeletal muscles that empty the veins toward the heart, the venous valves preventing its reflux to the periphery on relaxation; (*b*) the more frequent and ample respiratory movements and the contraction of the abdominal muscles that accelerate the circulation in the large veins of the abdomen and the thorax.

This greater venous return increases the strength of the systolic contraction, as the heart muscle fibers are distended by the greater diastolic filling of heart (Starling's law), and the distention of the right auricle reflexly increases the heart rate (Bainbridge's reflex).

Heart rate. The increase in heart rate (Fig. 213) produced by exercise is not due exclusively to the reflex decrease in vagal tone provoked by the distention of the right auricle by the greater venous return (Bainbridge's reflex). The pulse is accelerated as soon as exercise commences; the first cardiac cycle already shows a shortening of the diastole.[2] Probably this is due to a psychic effect on the vagal tone. Bainbridge's reflex and other factors, such as an increase in body temperature, sympathetic nerve impulses, adren-

[1] When the local increase of blood flow produced by local vasodilatation is not considerable, compensatory vasoconstriction of other areas maintains a constant cardiac minute volume.
[2] Bowen, W. P., *Am. J. Physiol.*, **11**, 59, 1904.

aline secretion, etc., act at a later stage. The heart rate increases rapidly and is stabilized at a maximum dependent on the intensity of the exercise, the age of the subject, his physical condition (training), the temperature of the environment, the atmospheric pressure, etc.

Fig. 213. Variations in systolic and diastolic blood pressure and in pulse rate during and after exercise.

The most important of these factors is the intensity of exercise; the heart rate increases with the intensity of the effort made. Exercise of the same intensity causes a greater increase in heart rate in young subjects that in older ones (Table 64). With age the highest heart rate produced

* Oxygen consumption increased to seven times the basal rate.

by maximum exercise decreases. From eighteen to twenty-five years this maximum rate is 190 to 210, at fifty it is down to 160 or 170, and at seventy it does not rise above 150.[1] Subjects in training have a smaller increase in heart rate than untrained subjects performing the same exercise. This is due mainly to the greater increase in the systolic output of the subjects in training.

[1] Dill, D. B., *Am Heart J.*, **23**, 441, 1942.

When the temperature of the environment is above 20°C., the heart rate in exercise reaches a higher level (Fig. 214). The barometric pressure influences the heart rate in exercise mainly because of a decrease in the partial pressure of oxygen causing varying degrees of anoxia, the effects of which will be studied later on.

After exercise has ceased, the heart rate diminishes, at first rapidly, then gradually until it falls to the resting level (Fig. 213).

Arterial blood pressure. The systolic blood pressure rises rapidly as soon as exercise is begun and reaches a maximum conditioned by the intensity of the exercise. It then falls a little and remains at a constant level, the height of which is conditioned by the intensity of the exercise. When the exercise is ended, the blood pressure falls rapidly and reaches the resting level before the heart rate becomes normal. The diastolic blood pressure has similar but less marked fluctuations;[1] after exercise it drops rapidly and then again rises. The pulse pressure is greater during exercise, and smaller immediately after, than it is at rest (Fig. 213).

Several factors cause these changes in blood pressure. The peripheral resistance diminishes during exercise[2] owing to vasodilatation in the active muscles, which is not completely com-

[1] Paterson, W. D., *J. Physiol.*, **66**, 323, 1928; Eskildsen, P., H. Gotzsche, and A. T. Hansen, *Acta cardiol.*, **4**, 199, 1949.

[2] Dexter, L. *et al.*, *J. Applied Physiol.*, **3**, 439, 1951.

pensated by vasoconstriction in other areas. The rise in blood pressure is due to an increase in the cardiac minute volume; therefore systolic and pulse pressure increase more than the diastolic pressure. Stabilization at a level slightly below the maximum observed at the beginning of exercise is probably due to compensatory mechanisms, *e.g.*, mechanical stimulation of the pressoreceptors of the aorta and carotid sinus, and stimulation of the chemoreceptors in the aortic and carotid bodies, by variations in the pH and other changes in the blood. Once the exercise is ended, the cardiac minute volume diminishes, and therefore the systolic and diastolic pressures fall. The rise in diastolic pressure a few minutes after the end of exercise has been attributed to constriction of the vascular territories, which were dilated during the exercise.[1]

FIG. 214. Effect of temperature on pulse rate after 10 min. exercise of different intensities. (*Dill, D. B., Am. Heart J., vol. 23, p. 441, 1942.*)

CHANGES IN THE BLOOD

Several changes are produced in the blood in the course of exercise. The magnitude of these changes is conditioned by the intensity and duration of the exercise. Plasma volume of circulating blood diminishes,[1] without any significant variation in red cell volume.[2] The viscosity, specific gravity, plasma-protein concentration, and red cell count increase. There are two mechanisms mainly responsible for these variations: (*a*) loss of fluid from the blood; (*b*) entrance of stored erythrocytes into the blood stream, a factor that is not of much importance in man. There is some loss of water through the skin (sweating) and the lungs (increased pulmonary ventilation), but the principal cause of the increase in the red cell count is the passage of water from the blood plasma to the tissues. The following factors facilitate this passage: (*a*) accumulation of metabolic products in the active muscles, which causes an increase in the osmotic pressure of the tissue fluids; (*b*) increased capillary permeability, caused by vasodilatation; (*c*) increase in the capillary filtration area, due to the opening of capillaries; (*d*) the rise in blood pressure. The increase in the red cell count, and therefore in hemoglobin concentration, increases the oxygen-carrying capacity of the blood.

FIG. 215. Changes in the concentration of the principal anions of the serum produced by exercise. (*Dill, D. B., J. H. Talbott, and H. T. Edwards, J. Physiol., vol. 69, p. 267, 1930.*)

[2] NYLIN, G., *Am. J. Physiol.*, **149**, 180, 1947.

Variations in the plasma concentration of the principal ions have been studied during exercise in normal subjects (Fig. 215), among whom the famous marathon runner De Mar was the only one in full training.[1] Bicarbonate and lactic acid varied inversely with each other. The degree of fatigue was related to the increase in lactic-acid concentration (Fig. 216).

Fig. 216. Changes produced by exercise in the concentration of lactic acid and bicarbonate (CO_2 combined at 40 mm. $HgCO_2$). Each subject had run 18 to 20 min. on a horizontal treadmill at 9.3 km. per hr. (*Dill, D. B., J. H. Talbott, and H. T. Edwards, J. Physiol., vol. 69, p. 267, 1930.*)

Moderate exercise causes insignificant changes, or none, in the blood sugar; hepatic glycogenolysis compensates for the increased utilization of muscle glycogen. Maximum exercise of short duration causes a 10 to 60 per cent increase in blood sugar,[2] probably due to glycogenolysis induced by sympathetic stimulation and secretion of adrenaline. Maximum and prolonged exercise, *e.g.*, a marathon race, exhausts the hepatic glycogen reserve and thus can provoke hypoglycemia.[3]

[3] Levine, S. A., B. Gordon, and C. L. Derick, *J. A. M. A.*, **82**, 1778, 1924.

CHANGES IN RENAL FUNCTION

After violent exercise of short duration (a 400-yd. race) the renal blood flow decreases and usually glomerular filtration and diuresis also decrease.[1] Urea clearance is depressed. The excretion of chloride and sodium diminishes considerably, while that of acids, ammonia, and phosphate increases.[2] Albuminuria is frequently observed, and when the lactic and pyruvic acid concentration in the blood rises sufficiently, these acids are also found in the urine.

CHANGES IN BODY TEMPERATURE

About 75 per cent of the energy used by the organism is converted into heat. This heat is lost through the skin and the lungs. Heat loss is increased in the following ways: (*a*) evaporation of water in the expired air by increased pulmonary ventilation; (*b*) evaporation of water on

[1] White, H. L., and D. Rolf, *Am. J. Physiol.*, **152**, 505, 1948; Chapman, C. B., *et al.*, *J. Clin. Investigation*, **27**, 639, 1948.

[2] Wilson, D. W., W. L. Long, H. C. Thompson, and S. Thurlow, *J. Biol. Chem.*, **45**, 755, 1925.

the skin (sweating); (*c*) increased convection by the movement of the exercising parts.

In exercise, when heat production exceeds the capacity to lose heat, the body temperature rises 1 to 1.5°C. This rise in temperature is not due to insufficient heat loss; it seems to be dependent on the heat-regulating nerve centers.[1] The increase in body temperature depends on the amount of exercise and individual factors such as the efficiency of temperature-regulating mechanisms. In some cases environmental factors, such as temperature and humidity, also play a part. The increase in body temperature facilitates the dissociation of oxyhemoglobin and accelerates metabolic processes, thereby aiding the adaptation of the subject to the conditions of exercise.

LASTING EFFECTS OF EXERCISE

Repeated exercise increases the working capacity of the organism.[2] The object of training is to acquire this increased capacity by increasing (*a*) strength; (*b*) resistance (sustaining an effort); (*c*) accuracy and sureness of movements.[3] The increase in strength is obtained by greater muscular development (hypertrophy and increase in motor units) and perhaps by physical and chemical adaptation: larger stores of glycogen and phosphocreatine, increased ability to dispose of lactic acid, greater activity of the oxidation-reduction mechanisms, etc.

Increase in resistance is conditioned by the capacity to respond to the greater oxygen demand created by exercise. Training results in hypertrophy of the heart and an increase in blood volume.[4] There is a diminished cardiac minute volume at rest, and an increase in the vital capacity of the lung, so that in exercise the minute volume and pulmonary ventilation can increase to a greater extent than in untrained subjects. The alkali reserve also increases, and thus larger amounts of lactic acid can accumulate in the blood. Trained subjects have a lower resting pulse rate than the untrained, because of an increase in vagal tone.

A more specific result of training is sureness and accuracy in the performance of movements. This is due in great part to improved neuromuscular coordination. The muscles respond more rapidly, and there is a more accurate adjustment in the reciprocal contraction and relaxation of synergical and antagonistic muscles. For this reason, to obtain better results in a particular type of exercise, *e.g.*, rowing, it is necessary to practice this type of exercise, besides undergoing the general training. The more accurate coordination of the different movements results in economy of effort, as only the appropriate muscles are contracted and only in the necessary measure; thus fatigue is delayed. The recovery period is also much shorter in trained subjects than in untrained ones.

Overtraining causes an abnormal condition in which several symptoms (lack of interest and initiative, sleepiness, irritability, etc.) and signs (tachycardia, arrhythmia, loss of weight, etc.) are prominent. This condition is usually due to a too-rapid increase of the effort demanded. The sudden interruption of training can also be harmful.

Measurement of physical fitness. The capacity to perform work is difficult to measure, because it is conditioned by many physical, psychic, and environmental factors. The appraisal of physical fitness is nevertheless of great importance in the physiology and hygiene of work, sport, and military training. This appraisal can be made by comparing the effect on certain physiological processes of (*a*) moderate exercise, and (*b*) maximum exercise, in subjects in good and in bad physical condition.

The performance of moderate exercise which can be kept up for a long time provokes in physically fit subjects less oxygen consumption, less marked rises in blood pressure and heart rate, lower increase in blood lactic acid and a larger systolic output, than in subjects in poor physical condition. After the exercise has ended, blood pressure and heart rate return to basal levels in less time in subjects in good physical condition than in those whose condition is poor.

Maximum exercise is kept up for a longer time by a subject physically fit than by one in poor condition. The former has a greater oxygen consumption, lower heart rate, greater systolic output, higher lactacidemia, and returns more rapidly after the exercise has ended to a basal blood-pressure and heart-rate level.

Subjects in good physical condition can therefore perform moderate exercise with small

[1] Pellegrini, A., G. Riva, and R. Margaria, *Boll. Soc. ital. biol. sper.*, **22**, 474, 1946; Asmussen, E., and M. Nielsen, *Acta physiol. Scandaniv.*, **14**, 382, 1947.

[4] Kjelberg, S. R., V. Rudhe, and T. Sjöstrand, *Acta physiol. Scandinav.*, **19**, 152, 1949.

adjustments in their physiologic equilibriums, and they can maintain a steady state at a higher level during a longer time than is possible for subjects in poor condition. Recovery of basal conditions is also more rapid in subjects in good condition than in those in bad condition.

Several methods of measuring physical fitness have been proposed.[1] The duration or the amount of work performed in maximal exercise can be measured, or the changes provoked by a certain amount of work on the oxygen consumption, lactacidemia, oxygen debt, blood pressure, etc., can be determined. Usually the heart rate is counted during and after exercise.

THE ENERGETICS OF EXERCISE

Muscles are machines that convert chemical energy into mechanical work and heat. An outstanding feature of exercise is the great amount of energy the organism can develop. For example, a subject weighing 75 kg. in complete rest has an output of about 1.2 cal. per min.; this output is increased to 10 or 15 cal. per min. in violent exercise.

The efficiency of the organism considered as a machine for converting energy can be measured by determining the energy output (either in a calorimeter or by calculating it from the oxygen consumption) and the work performed. The net maximum efficiency in man is around 25 per cent (Table 65).

Table 65. Maximum Efficiency of Engines, Horse, and Man

	Efficiency, %
Steam engine	15
Gasoline motor	18
Horse	24
Man (climbing stairs)	25
Diesel motor	35

Source: BRODY, S., and E. A. TROWBRIDGE, Bull. 383, Agricultural College, University of Missouri, 1937.

To obtain the net efficiency, the energy consumption at rest (BMR, basal metabolic rate) must be subtracted from the total energy consumption. Thus gross efficiency is

$$E_g = \frac{100W}{H}$$

where W is work performed and H is total energy. Net efficiency is

$$E_n = \frac{100W}{H - BMR}$$

[1] TAYLOR, C. L., *Ann. Rev. Physiol.*, **7**, 599, 1945.

Net efficiency is conditioned by the type of work done (ergometer, treadmill, carrying a load, running, etc.), training, coordination of movements, speed, etc. For example, Fig. 217 illustrates the effect of speed on efficiency. The curve responds fairly accurately to Hill's equa-
FIG. 217. Efficiency and speed of exercise. The subject climbed a staircase; the greatest efficiency corresponded to a speed of 50 steps per minute. (*Lipton, H., J. Physiol., vol. 57, p. 337, 1923.*)

tion for efficiency and duration of muscular contraction, and it shows that maximum efficiency is obtained only within a fairly narrow range of speed.[1] These results have important applications in the physiology of exercise; *e.g.*, walking is most economical when performed at a rate 120 paces per minute.

Sources of muscular energy. At one time protein was thought to be a source of energy for muscular contraction, because the uric acid and creatinine excreted in the urine increase during heavy exercise. Proof has now been obtained that these nitrogen compounds are simply a sign of muscular wear and tear caused by contraction. In any case, protein could supply only a very small part of the energy used in performing mechanical work. Carbohydrate and fat must therefore be considered as possible sources of energy.

Observations on the respiratory quotient have given valuable information in this respect. The respiratory quotient increases in exercise, in relation to the intensity of exercise (in violent exercise the RQ is above 1 because of the excess CO_2 eliminated). This shows that there is a greater consumption of carbohydrate. Never-

[1] HILL, A. V., *Lancet*, **281**, 947, 1951.

theless, in prolonged exercise the RQ seldom rises to the value of 1, and when the diet is poor in carbohydrate, there not only is a low RQ when resting, but also the rise of the RQ provoked by exercise is less (Table 66).

Table 66. The Effect of Exercise on the Respiratory Quotient

Previous diet	*At rest before exercise*	*During exercise*	*After exercise*
Carbohydrate..........	0.85	0.90	0.78
Carbohydrate-poor......	0.79	0.82	0.75

Source: BENEDICT, F. G., and E. P. CATHCART, Carnegie Institution, Pub. No. 187, Washington, D. C., 1913.

A carbohydrate-rich diet is therefore advisable for increasing the capacity for work. Moreover the maximum RQ diminishes in successive periods of exercise. All these results have led to the conclusion that not only carbohydrate but also fats are sources of energy in muscular contraction. The way in which muscle obtains energy from fat is not yet known; it is still doubtful whether muscles can utilize storage fats directly, or whether these must first be modified or converted into carbohydrate.[1]

Appetite for fat and protein is greater in athletes and persons doing heavy manual work than in those with sedentary habits. An increased desire for fats is perhaps due to the fact that these substances are an economical source of energy. The larger consumption of protein is perhaps caused by the high vitamin B complex content of meat. Individuals in training are easily fatigued and their capacity for work is small if they are fed a diet poor in vitamin B complex. Normal capacity for work is restored by supplementing the diet with B complex preparations.[2]

Alcohol, caffein, cocaine, strychnine, and nitroglycerine have been tested in trained athletes, but they do not raise the efficiency of persons in good condition.[3]

FATIGUE

Fatigue results from muscular activity and from the activity of the nervous system (mental work, etc.). Frequently both types of fatigue combine in varying proportions. The consequence is a diminished capacity for work.

In muscular exercise fatigue is due to the accumulation of metabolic products, the exhaustion of energy-yielding substances, and other muscular, respiratory, and circulatory phenomena. Mental fatigue is more difficult to appreciate objectively. The following can be mentioned among causes of this type of fatigue: anxiety, nervous tension, monotony of the task, noise, vibrations, lack of adequate rest periods, etc.

INDUSTRIAL PHYSIOLOGY

The results obtained by observing the physiologic changes in the organism produced by exercise have been applied to the study of working conditions in factories, the army, etc. Thus a new field has been opened, that of industrial physiology. Its main object is to determine the optimal conditions for obtaining maximum efficiency and for retarding the onset of fatigue. This is of great importance in industry. The great variety of types of work in industry and the environmental circumstances (climate, light, ventilation, etc.) in which it must be performed present many problems to the physiologist.

Each type of work has its particular problems, and several attempts have been made to classify work. In one classification three types of work are differentiated according to whether strength (stone breaking, foundry), endurance (common labor), or speed (packing, typewriting) is the predominant feature. The environmental factors (barometric pressure, temperature, humidity, etc.) are quite as important as the type of work. Many examples could be given of the applications of physiological knowledge to the solution of problems of this nature. For example, laborers working on the Boulder Dam in hot weather frequently suffered from cramps. A physiological study of these workers showed that they sweated profusely and therefore lost water and sodium chloride in great amounts. They drank large quantities of water, thus replacing it but not the salt. The administration of salt immediately cured the cramps and prevented not only considerable suffering but also

the loss of many working hours with the consequent economic disturbance.

This branch of physiology received great impetus during the Second World War, not only with respect to work in the factories, which was of fundamental importance, but also with respect to the activity of soldiers, because the variety of battle fronts in all latitudes created many problems. The fighting conditions of an infantry soldier in the Russian winter were widely different from those of a tank driver in the African desert or of a marine disembarking on an island in the Pacific. The advance of aviation has been a special source of problems for physiology and medicine.

One of the aims of industrial physiology is to find out what kind of work is suited to the capacity of the workman, his physical condition, and the environment in which he works. If the effort is an excessive one, it will be harmful; if it is below the workman's capacity, it will be economically inefficient. In this respect training and fatigue have a different significance in industry and in exercise. Training can be directed to increase strength and endurance, but it will give better results if its object is to acquire perfection in the coordination of movement. Ability depends to a great extent on inborn factors, but its development by training has a considerable stability. As Abramson says, "Man needs to learn how to ride a bicycle only once in his life, while strength and endurance must be built up each year."

Psychological factors are quite as important as physical ones in the onset of fatigue, if not more so. Not only the conditions in the factory (duration and nature of the work performed, speed, rhythm, etc.), but also those outside the factory (rest, home conditions, etc.) are important. Fatigue can be delayed by many devices, such as adequate rest periods, music, competition between groups, knowledge of the significance of the task, etc.

AVIATION PHYSIOLOGY[1]

The remarkable technical progress in aviation has created many problems in physiology. Airplanes are built that can climb more than 40,000 ft. (12,000 m.) in a few minutes, fly at 600 miles (1,000 km.) an hour, and nosedive at speeds near those of sound. Jet-propulsion planes that can fly above the atmosphere may be built in the near future. Already planes have flown at heights above 70,000 ft. (22,000 m.), *i.e.*, an altitude equivalent to 95 per cent of the atmosphere. This type of flying has presented new problems, *e.g.*, rapid displacement through the atmosphere when ascending or descending (heating of the plane, acceleration, deceleration). Moreover, certain vital properties of the atmosphere no longer exist: there are no atmospheric gases; ultraviolet and cosmic rays are not filtrated; the plane is in a dark vacuum and may collide with meteorites. The pilots of these planes must be especially protected to be able to resist the conditions of flight. Anoxia, sudden changes in barometric pressure, cold, and acceleration are some of the factors creating outstanding problems that will be considered here.

Anoxia. Historically anoxia was the first obstacle man had to overcome in his conquest of the air. Remarkable experiments by Paul Bert with a pneumatic pump, performed on animals and man, proved that the disorders observed in the course of balloon ascensions were due not to the fall in barometric pressure, but to the fall in the partial pressure of oxygen—therefore, to lack of oxygen.

The conditions governing the combination of hemoglobin with oxygen at different partial pressures of oxygen (see Sec. III, Respiration) are such that up to a height of 13,000 ft. (4,000 m.) there are no serious effects on the organism. At 20,000 ft. (6,200 m.) the atmospheric pressure is 380 mm. Hg, one-half that at sea level, and the oxygen partial pressure is also half the normal (Fig. 138). At this oxygen pressure the blood is insufficiently oxygenated and signs of anoxia are observed. To prevent anoxia the oxygen pressure must be increased. This can be done in one of two ways: (*a*) by increasing the percentage of oxygen in the air breathed by the pilot from an oxygen mask, such as the widely used Boothby, Lovelace, and Bulbulian (BLB) model or the more elaborate ones with regulatory valves; (*b*) enclosing the pilot in a hermetically sealed cabin or in a special suit in which air, more or less rich in oxygen, is kept at high pressure. As a safety measure the military authorities in the Second World War

[1] Armstrong, H. C., "Principles and Practice of Aviation Medicine," Williams & Wilkins, Baltimore, 1939; Gemmill, C. L., "Physiology in Aviation," Charles C Thomas, Springfield, Ill., 1943.

obliged flying personnel to inhale oxygen at any height above 13,000 ft. (4,000 m.).

Gaseous embolism. This is another physiological problem created by technical progress. The rapid ascent of modern planes is accompanied by a correspondingly rapid fall in barometric pressure. This causes nitrogen dissolved in the blood to be released in gaseous form, and the bubbles thus produced can clog the small blood vessels (gaseous embolism).

The blood and the body fluids are always saturated with the gases of the atmosphere, because the blood is exposed to these gases as it passes through the lungs. They are dissolved in the plasma according to their solubility and partial pressure. As nitrogen forms 79 per cent of the air, a relatively large amount of it is dissolved in the blood (1.7 cc. of N_2 per 100 cc. at 1 atmosphere). An equilibrium is established between the N_2 in the air, the blood, and the body fluids. When the barometric pressure increases (in divers it can be up to 5 and even 7 atmospheres) the partial pressure of N_2 increases in the inspired air and in the lungs, and therefore also in the blood and in the tissues, and a new equilibrium is established. If the barometric pressure then falls gradually to the normal level, the nitrogen pressure will be higher in blood than in the air, and N_2 leaves the blood as it passes through the tissues. If the barometric pressure falls gradually, no disturbance occurs, but if it falls suddenly so that the partial pressure of N_2 in the tissues is twice that in the air, N_2 is released in gaseous form and bubbles appear in the blood. As N_2 is more soluble in fats than in water, bubbles are more easily formed in tissues with a large fat content, *e.g.*, the central nervous system. These bubbles are a serious obstacle to the passage of blood in the small arteries, and the areas nourished by the obstructed vessels are the site of disturbances of lesser or greater severity. At first there is a sensation of itching in the skin, then pains of increasing severity in the chest and joints, shooting pains along the nerves, dyspnea, cyanosis, coughing, paralysis, etc. These signs and symptoms have often been observed in divers coming up too rapidly to the surface after having been submerged for a certain time at a pressure of 4 to 5 atmospheres (caisson disease). It is therefore necessary to raise them to the surface gradually so they can eliminate the excess N_2 dissolved and a new nitrogen equilibrium can be established between the air and the tissues without the formation of N_2 bubbles. This method was proposed by Haldane many years ago and gives excellent results, but the equilibrium is reached only after a relatively long time. More recently the breathing of air in which N_2 has been replaced by oxygen or helium has been proposed.

An aviator ascending rapidly is in the same situation as a diver coming up to the surface. For example, at 42,000 ft. (12,800 m.) the barometric pressure is 150 mm. Hg or about one-fifth of 1 atmosphere. Gases dissolved in the blood at the normal pressure will be eliminated, and a new equilibrium will be established at this barometric pressure, as was stated above. Oxygen and CO_2 rapidly combine with hemoglobin and the alkaline reserve, but N_2 must go from the tissue fluids to the plasma and from thence to the alveolar air. If there is a very rapid ascent, as frequently occurs in fighting conditions, the equilibrium between N_2 in the tissues and the air cannot be established gradually, so this gas is released and forms bubbles, with the results described. Cabins that can be kept at constant pressure have solved some of these problems, but they may accidentally lose pressure.

Zuntz suggested many years ago that by breathing pure oxygen part of the N_2 dissolved in the body fluids could be rapidly eliminated. In 1 hr. about 50 per cent of the dissolved N_2 is displaced, but it takes over 5 hr. to displace the remaining 50 per cent. This is due to the fact that dissolved nitrogen is much more rapidly displaced from the body fluids than from the tissues, especially those with a high fat content, where there is slow circulation and a large amount of gas dissolved (adipose tissue). Exercise while breathing oxygen hastens the elimination of N_2 because it speeds up the circulation (increase in cardiac minute volume, decrease in circulation time, etc.). A pilot can thus eliminate a large proportion of the nitrogen dissolved in his body fluids before going up and can thus diminish the risk of gaseous embolism. There are individual differences in this respect, which can be demonstrated in low-pressure chambers.

Disturbances in the ear. In the course of one of the first ascensions in a balloon, December 17, 1873, the pilot felt acute pain in the ears. Anyone who has traveled in an airplane, or even gone up or down in a rapidly moving elevator, has experienced such disturbances.

The pain is due to the difference between the pressure on the outside of the eardrum and the pressure in the middle ear, *i.e.*, on the inside of the eardrum. The eustachian tube, which goes from the middle ear to the pharynx, is usually closed but opens on swallowing or yawning. When an airplane rises, the pressure on the outside of the eardrum falls below that in the middle ear, and the tympanic membrane bulges out; this distention is the cause of the pain. When the difference in pressure between the middle ear and the external environment is about 15 mm. Hg, the eustachian tube is opened, and thus the pressure on each side of the eardrum becomes the same. A click is heard when this occurs. It is enough to perform the simple act of swallowing to prevent all this. In the opposite case, *i.e.*, when the atmospheric pressure is greater than that of the middle ear, as when descending in an airplane or on diving into water, the eustachian tube acts as a valve and does not allow the passage of air from the mouth to the ear; therefore if the eustachian tube is not opened by swallowing, yawning, or crying out, the tympanic membrane will be more and more pushed in toward the internal wall of the middle ear. If the descent is rapid enough (about 3,000 ft. per min.) the tympanic membrane can be ruptured. A noise like that of an explosion is heard, and a sensation of having been knocked on the head is experienced.

Airplanes when nosediving descend at a tremendous velocity. If the pilot does not keep his eustachian tube open by repeated swallowing, or if he has a catarrh that obstructs it, the tympanic membrane will be ruptured, pain will be felt, and a more or less severe hemorrhage may occur, with a resultant deafness. For this reason pilots should not fly when suffering from a cold, and if they are obliged to do so, they should ascend or descend gradually to avoid sharp differences in pressure between the atmosphere and the middle ear.

Cold. Another problem that must be considered is the protection of the aviator against cold. For every 1,100 ft. (330 m.) of ascent, a decrease in temperature of about 2°C. takes place, up to 38,000 ft. (11,500 m.), the upper limit of the troposphere; at higher altitudes (stratosphere) the temperature remains constant at −55°C. The organism reacts against cold by intense cutaneous vasoconstriction; by diminishing the secretion of sweat, thus decreasing heat loss; and by involuntary muscular contractions (shivering), thus increasing heat production. When there is intense cold or prolonged exposure, symptoms of depression, indifference, and lethargy appear, and finally the subject dies. As fighting planes must rise rapidly to high altitudes where their efficiency is greater, it has been necessary to solve the problem of keeping the pilot warm while flying or parachuting at a height of 32,000 to 42,000 ft. (10,000 to over 12,000 m.) where the temperature is between −45 and −55°C. Especially heated suits have been used for this purpose.

Effects of acceleration. The tremendous velocities developed by jet-propelled planes have created very serious problems. Planes are now built with a speed exceeding that of sound (800 miles per hour); but change in speed, *i.e.*, acceleration, not speed itself, is the cause of the most serious problems in aviation physiology. The results of acceleration can be instantaneous, serious, and even dramatic.

The greatest degrees of acceleration occur when there is a change in the direction of flight, and they are due to pressure on the wings of the machine. For example, when a plane nosedives the velocity is more or less uniform while the plane flies in a straight line, but when the direction of flight changes there is an increase in weight, due to the new force applied at right angles to the original direction. The same thing occurs in "inward" looping. The resultant force of this acceleration is transmitted parallel to the longest axis of the pilot's body when he is in the usual position in a plane—in this case, from the seat to the head. This causes, among other disturbances, an accumulation of blood in the abdomen and a decrease of the flow of blood to the heart and head. The result is a fall in blood pressure and cerebral anemia. The visual apparatus, retina, optic nerves, and nerve centers are particularly sensitive to lack of blood, so an outstanding result of acceleration is a visual defect, consisting in loss of vision known as "blackout" (called *Vorhang*, curtain, by the Germans). If the cerebral anemia is sufficiently prolonged, the pilot loses consciousness. In "outward" looping, on the contrary, blood accumulates in the head and the pilot "sees red" ("red-out"). The acceleration most frequently endured by military pilots is equal to four times the force of gravity and is expressed as 4*g*. An ordinary pilot can endure 3 to 6*g*, while those

with considerable experience can tolerate up to 7 and 8*g*.

When the force of acceleration is transmitted at right angles to the main axis of the body, its effects are not so serious. Thus if the pilot lies down during the descent, when the plane straightens out the force of acceleration will act in a transverse direction to the long axis of the pilot's body. Hence the adoption of this position would solve in great part the difficulties encountered; unfortunately it is not easy to control the machine when lying down. The blackout is due mainly to the accumulation of blood in the abdominal viscera. Pilots are therefore advised to bend forward when nosediving, pressing the chin against the chest, and to cry out. These actions if forcibly carried out are accompanied by widespread muscular contraction, including the abdominal muscles, and congestion in the head. Abdominal pressure can also be increased by compressing the abdomen with a special pneumatic belt, or by preventing venous stasis in the lower limbs, but the devices so far used for these purposes are not very satisfactory.

The physiological problems resulting from the constant progress of aviation have brought about a race between the physiologists and the engineers. The new machines submit the pilots to increasingly severe abnormal conditions: great speed, rapid ascent, nosedives, centrifugal force, acceleration that amounts to several times the force of gravity, prolonged flight, very high altitudes with the consequent low temperature and low oxygen pressure, and finally rapid changes in barometric pressure. Physiologists have studied the effects of these abnormal conditions on the organism and have found ways of preventing most of the accidents that these conditions can provoke.

CHAPTER 48

The Body Temperature and Its Regulation

The significance of animal heat. The evolution of heat in animals can be considered from two points of view: (*a*) heat is the final and irreversible form in which energy obtained from the oxidation of foodstuffs is eliminated from the body; (*b*) a certain temperature level is a necessary condition for the maintenance of an adequate rate in biologic processes.

In the resting organism all the energy obtained from oxidations is finally converted into heat. Thus, if the equivalent of 1800 kg.-cal. of foodstuffs is oxidized, 1800 kg.-cal. will be eliminated as heat, when the body temperature is neither rising nor falling. The performance of mechanical work requires additional chemical energy. Only 20 to 25 kg.-cal. out of every 100 of this additional energy is converted into work; 75 to 80 kg.-cal. is lost as heat.[1] For example, the heat production of a subject at rest is 2000 kg.-cal. in 24 hr. During the same period he performs work and for this purpose 1000 kg.-cal. is spent, bringing the total up to 3000. If the mechanical efficiency is 25 per cent, 750 of the additional calories will be given out as heat and only 250 will be converted into mechanical energy.

The maintenance of a certain temperature is of vital importance to the organism, because all biologic processes are conditioned by temperature. At 0°C. these processes slow down considerably, or even stop; as the temperature rises, their velocity increases up to a maximum at an optimum temperature. Higher temperatures provoke disturbances and even death. In mammals the central nervous system ceases to function at 44 to 45°C. and the heart stops beating at 48°C. The van't Hoff–Arrhenius law, which governs chemical reactions,[1] is valid for physiologic processes; *e.g.*, a rise in temperature of 10°C. causes a twofold to threefold increase in pulse rate, oxygen consumption, etc. The law can be applied to animals only within certain limits, because high temperatures damage the tissues (Figs. 218 and 219).

[1] The efficiency of an organism considered as a machine is given by the ratio of the energy converted into work (W) to the total energy evolved (H) minus resting metabolism (BMR). Net mechanical efficiency, $E_n = \frac{100W}{H - BMR}$, varies from 20 to 25.

[1] A rise of 10° C. increases the velocity of chemical reactions two to three times, *i.e.*, the temperature coefficient (Q_{10}) is from 2 to 3.

Two magnitudes must be considered when dealing with heat: (*a*) quantity of heat, measured in calories, which can be summated; (*b*) temperature, measured in degrees of a centigrade or Fahrenheit scale, which cannot be summated. For example, if 1 liter of water at 37°C., holding therefore 37 kg.-cal., is added to another 1 liter of water at 37°C., there will be 2 liters of water holding 74 kg.-cal., at 37°C.—not at 74°C The specific heat is the amount of heat absorbed by 1 gram of a body when its temperature is raised 1°C. The specific heat of water is considered as 1; that of the human body is 0.83. Variations in heat intensity, *i.e.*, temperature, and not in heat quantity, modify the rate of physiologic processes.

According to their capacity to regulate their body temperature, animals are classified *poikilothermic* and *homoiothermic*. The body temperature of poikilothermic animals varies with the temperature of the environment; thus their vital processes are easily modified by changes in the environmental temperature. Inverte-

brates, fishes, amphibians, and reptiles are poikilothermic; their temperature is usually a few degrees above that of the environment. Homoiothermic animals maintain their temperature constant within narrow limits, and changes in environmental temperature provoke only slight oscillations in their body temperature. This constancy is achieved by the regulation of heat production and heat loss. Homoiothermic animals are similar to a thermostat, the temperature of which is kept constant by regulating the mechanism that heats it and the loss of heat from it. Newborn homoiothermic animals are less resistant to cold than adults, because the nervous system is not completely developed at birth. For example, white rats a few days old placed at 3 to 9°C. cease to consume oxygen, their hearts stop beating, and they remain without movement. If they have not been kept at this low temperature for more than a few hours, they will return to their normal condition a few minutes after being warmed. Hibernating animals are homoiothermic from spring to fall, but in winter when the environmental temperature is below 10°C. (50°F.) their body temperature falls to a level little above the outside temperature, their vital processes slow down, and they are lethargic until the following spring. They are awakened from their winter sleep when the outside temperature rises above 15°C. (59°F.). They also wake when it falls below 2°C. (35.6°F.).

FIG. 218. Effect of changes of temperature on the oxygen consumption of smooth muscle (isolated guinea pig uterus). The dotted line is the theoretical curve for an increase in O_2 consumption of 2.5 times for every temperature increase of 10°C. (*Lovatt-Evans, C., "Starling's Principles of Human Physiology," 7th ed., J. & A. Churchill, London, 1938.*)

THE TEMPERATURE OF THE BODY

In medical practice body temperature is measured by placing a thermometer under the tongue, in the axilla, or in the rectum. Rectal temperature[1] in man has a daily oscillation from 35.9 to 37.3°C. (96.5 to 99.1°F.); the average is usually given as 37.0°C. (98.6°F.), and even 38°C. (100.4°F.) is not abnormal in warm climates. Rectal temperature is more reliable
FIG. 219. Curve representing activity of vital processes. There is an increase up to an optimum temperature, above which activity diminishes; at even higher temperatures the cells are damaged and die.

[1] The thermometer must be introduced 6 cm. or more into the rectum to obtain reliable data. Rectal temperature of birds is 40 to 42°C. (104 to 107.6°F.); it is lower in mammals, 35 to 40°C. (95 to 104°F.), usually 39°C. (102.2°F.); in the dog and cat it is 38.5 to 39°C. (101.3 to 102.2°F.); in the horse, 37.5 to 38°C. (99.5 to 100.4°F.); in the ox, 38.2 to 38.7°C. (100.7 to 101.6°F.)

than axillary or buccal temperature, but for esthetic reasons it is not usually taken. Nevertheless when there is any doubt of the existence of fever the rectal temperature should be taken; *e.g.*, in certain cases of tuberculosis it is possible to discover a febrile condition only by taking the rectal temperature every two hours.

If the temperature is taken in the axilla, the thermometer should be left in place for 5 or even 10 min. with the arm held tightly against the thorax. In small children it is easier to take the temperature in the groin. The temperature of the axilla is usually 0.2 to 0.4°C. (0.36 to 0.72°F.) below the temperature in the mouth and 0.5 to 1°C. (0.9 to 1.8°F.) below that of the rectum. It varies daily between 36.2 and 36.9°C. (97.2 and 98.4°F.), with an average of 36.6°C. (97.8°F.), exceptionally reaching to 37.2°C. (98.96°F.). The temperature in the mouth is taken by placing the thermometer under the tongue and keeping the mouth closed; it is 0.3 to 0.5°C. (0.54 to 0.90°F.) below rectal temperature. If hot or cold beverages have been taken, the temperature of the mouth may be above or below normal for a short time.

The temperature of the skin varies in different parts of the body. The temperature of the viscera is 1 to 1.5°C. (1.8 to 2.7°F.) above the temperature in the axilla; it is highest in the liver. The temperature of arterial blood in the limbs has been measured by introducing into the artery a thermocouple in a plastic tube. It varies in different arteries and is modified by the temperature of the environment, the pulse frequency, and the position of the limb.[1] The temperature of venous blood varies more; in the veins of the skin and limbs it is lower than in the arteries. In the vena cava it increases as the blood from the viscera enters the vein and reaches a maximum at the level of the suprahepatic veins. The blood is cooled as it passes through the lung; for this reason it is warmer in the right ventricle than in the left ventricle.

The temperature of the skin varies with the temperature of the environment, the humidity of the atmosphere, the ventilation, and the amount of clothing, on one hand, and with the state of the circulation in the skin and the evaporation of sweat, on the other.

Diurnal variation. The temperature of man has a typical daily variation. It is at its maximum between 5:00 and 8:00 P.M. and at its minimum between 2:00 and 6:00 A.M. Subjects with fever usually have a maximum temperature in the evening also, but in some cases this is not so; the peak will then be discovered by taking the temperature every two hours. The temperature curve is related to variations in muscular activity and metabolism, which are at a maximum in the evening and at a minimum in the early morning. An inversion of the usual cycle is seen in some cases, *e.g.*, in some nightworkers or in subjects traveling around the world, who continue with their usual rhythm, although the day in the place from which they started corresponds to the night in the antipodes. Night birds have a maximum temperature at night.

Other temperature variations. Body temperature is not very stable in the newborn; a hot or a cold bath causes a rise or a fall in temperature. Stability increases with age and is at its maximum in normal adults. In old age the temperature tends to be lower. In women there is a variation related to the menstrual cycle. At the moment of ovulation the temperature falls (about 0.2°C.). It rises 0.1 to 0.4°C. during the second half of the cycle, owing to the effect of the luteal hormone. During menstruation it again falls (0.6°C.). There is a subnormal temperature in subjects with a low metabolic rate, *e.g.*, in undernourishment, starvation, myxedema, or hypophyseal insufficiency. The body temperature is frequently a little above normal in hyperthyroid subjects, owing to high muscular tone and tremor. It is also high on very hot days. It rises a little after a meal and during exercise. Strenuous exercise can produce a transitory rise up to 39 or 40°C. In some cases of tetanus, skin temperature continues to rise for some time after death.

The lower limit of body temperature compatible with life in man is 27 to 29°C. (80.6 to 84.2°F.). Exceptional cases have been reported of survival after the body temperature had fallen to 24 and even 20°C. (75.2 and 68°F.). An increase in temperature to 42 or 43°C. (107.6 or 109.4°F.) is seldom observed. A rise of temperature to 44 or 45°C. (111.2 or 113° F.) produces fatal disturbances in the central nervous system.

THE REGULATION OF THE BODY TEMPERATURE

The body temperature results from the balance of heat produced (thermogenesis) and heat

[1] BAZETT, H. C., *Am. J. M. Sc.*, **218**, 483, 1949; EICHMA, J. W., *et al.*, *J. Clin. Investigation*, **30**, 353, 1951.

lost (thermolysis). Heat production is the result of the chemical processes of metabolism; therefore its regulation is sometimes called the *chemical regulation* of temperature. Heat is lost by physical processes, and its regulation is therefore called the *physical regulation* of temperature. The temperature level or homoiothermia (thermal homeostasis) is dependent on a well-controlled equilibrium between the chemical and physical processes of temperature regulation. This equilibrium can be represented (Fig. 220) by a balance, on one plate of which the processes of heat production are placed, and on the other those of heat loss. An increase in heat production tends to raise the temperature, while an increase in heat loss tends to lower it.

FIG. 220. Factors in the regulation of temperature. (*Du Bois, E., Lane Medical Lectures, Stanford University Press, Stanford, California, 1937.*)

THE CONTROL OF HEAT PRODUCTION

The amount of heat produced depends on the metabolic rate and therefore on the rate of exothermic chemical processes. Some of the intermediary exothermal chemical reactions are anoxybiotic (*i.e.*, not oxidations), but ultimately all the heat produced in the body comes from oxidations.

The following (in order of importance) are the principal mechanisms that regulate heat production (chemical regulation of temperature): (*a*) phasic muscular activity (exercise, shivering); (*b*) muscle tone; (*c*) the specific dynamic action of foodstuffs; (*d*) changes in the basal metabolic rate.

Glandular tissue, especially the liver and in second place the kidney, produces as much heat per unit weight as resting muscle or more, but the muscles are the most important factor in heat production. This is due to two reasons: (*a*) muscles form approximately one-half of the body mass; (*b*) muscular activity causes an increase in the metabolic rate, which can rise to from 4 to 10 times the resting level in strenuous exercise. Of the extra energy evolved in exercise, only 20 to 25 per cent is converted into mechanical energy; 75 to 80 per cent is given out as heat.

Muscle tone is a form of muscular activity that normally produces a large amount of heat and contributes to maintain a normal body temperature. It is increased by cold and emotion, even when there is no perceptible change. This can be demonstrated by registering the action potential of the muscle fibers; a considerable increase in asynchronous contractions

of motor units will thus be revealed.[1] Cold also stimulates voluntary movements in man and many animals, but the fundamental processes in the increase of heat production in response to cold are tremor and shivering. When a subject is placed in a cold environment there is no definite increase in heat production until shivering begins; then there is an immediate and considerable increase in oxygen consumption and heat production. This mechanism is much more important than any other in the response to cold.

FIG. 221. Effect of temperature on metabolism.

Phasic (movement, shivering) and tonic muscular contractions are controlled by the nervous system. Therefore if nervous activity is suppressed by anesthesia or the muscles are paralyzed with curare, heat lost by the body is not adequately replaced and the temperature falls. This fall is marked and rapid in animals intoxicated with curare.

Heat production is at a minimum in the majority of mammals when the outside temperature is 28 to 30°C. (82.4 to 86°F.). This is known as the critical temperature. At temperatures below 28°C., heat production increases so as to compensate the loss of heat, and at higher temperatures it also increases because there is a slight rise in body temperature, which increases the velocity of the chemical reactions in the organism according to van't Hoff's law. In man there is a fairly wide range of critical temperature, *i.e.*, environmental temperature conditions that have no influence on heat production. This range is given as 22 to 35°C. (71.6 to 95°F.) by Du Bois and 25.5 to 29°C. (77.5 to 83.4°F.) by Winslow and Herrington. In a damp atmosphere heat production and rectal temperature begin to increase when the temperature rises to 30 or 33°C. (84 or 91.4°F.). The increase in heat production caused by cold is considerable; it may be three and even four times the BMR. The highest metabolic rate provoked by cold in homoiothermic animals has been called "vertex metabolism."[1] In poikilothermic animals the metabolic rate increases as the temperature rises from 0 to 30°C. (32 to 84°F.) (Fig. 221).

Cold baths increase heat production because they cause movements and shivering. Hot baths increase heat production because they raise the body temperature. An increase in the temperature of the environment causes an increase in heat production only when it also causes a rise in body temperature of a few tenths of a degree centigrade.

The BMR increases in some species (*e.g.*, the rat) after they have lived for some time in a cold environment. This response is accompanied by changes in the liver, thyroid, adrenals, and other organs. When these animals are again placed in a warm environment (*e.g.*, if rats are taken from a room at 15°C. to another at 25°C.) the BMR returns to the lower level only after several days. Time is needed for the glandular changes to take place before the BMR is stabilized at a level corresponding to the environmental temperature.

The specific dynamic action of foodstuffs increases heat production. The effect of protein (30 per cent) is greater than that of fat (6 per cent) or carbohydrate (4 per cent). Probably this is the reason for the tendency to consume high-protein diets observed in countries with a

[1] BURTON, A. C., and D. W. BRONK, *Ann. Rev. Physiol.*, **1**, 109, 1939.

[1] GIAIA, M., *Compt. rend Soc. de biol.*, **90**, 1087, 1924; **92**, 364, 1925; **93**, 646, 1925.

cold climate. In such climates there is also a tendency to increase the amount of fat in the diet, especially if hard manual labor is performed, because fat has a high caloric value in small bulk. In several species, cold or a decrease in body temperature provokes a larger consumption of food, while heat or a rise in body temperature tends to diminish food consumption.

The increase in heat production and body temperature (fever) of infectious diseases will be considered later.

The Control of Heat Loss

All bodies when placed at a temperature below their own lose heat by conduction, radiation, convection, and vaporization of water. These processes also take place in homoiothermic animals, and the mechanism by which they are controlled is known as the physical regulation of temperature. In man the amount of heat lost depends on the body surface, the relation between the body temperature and the environmental temperature, and the humidity of the atmosphere. Most of the heat is lost by radiation, evaporation, and convection.

Conduction of heat. This consists in the transmission of heat from one molecule to another in a solid, liquid, or gaseous body. It depends on the conductivity of the body and the difference in temperature between the two points in question. Heat conductivity is measured by the amount of heat (in calories) transmitted in one second from one side to the opposite side of a cube of 1 cu. cm. of the substance, when there is a difference in temperature of 1°C. between the two sides. Differences in conductivity cause two bodies at the same temperature to appear to be at different temperatures when brought into contact with the skin; *e.g.*, wood (a poor heat conductor) appears to be warmer than metal (a good heat conductor) at the same temperature, because more heat is lost from the skin to the latter than to the former. Water is a relatively poor heat conductor, and air a very poor one. Man loses very little heat by conduction when in air; he loses more when he is submerged in water, but a larger amount may be lost by placing the body in contact with metals or a cold floor.

The specific heat of the body. The specific heat of pure water is the unit of specific heat, *i.e.*, the amount of heat needed to raise 1 kg. of water 1°C. is 1 kg.-cal. The specific heat of the human body is 0.83. A subject weighing 70 kg. with an average body temperature of 37°C. holds 2150 kg.-cal. ($70 \times 37 \times 0.83 = 2150$). The large proportion of water in the organism causes thermal changes to proceed at a low rate. Therefore, even if man had no mechanisms of temperature regulation, a large amount of heat would have to be gained or lost to cause a rise or a fall of 1°C. in temperature. In the example just given it would have to be 58 kg.-cal. ($70 \times 1 \times 0.83 = 58.1$). Water has a very high specific heat compared to that of air, which is from 0.169 to 0.237; moreover, it is a better heat conductor. Therefore a subject submerged in water at 0 to 5°C. loses much more heat, suffers more from cold, and dies sooner than when exposed to air at the same temperature.

Radiation. Radiant heat is transmitted by electromagnetic waves at the speed of light (300,000 km. per sec.). These waves show the same phenomena as light, *i.e.*, interference, reflection, refraction, and polarization. The heat from the sun is transmitted to the earth by these waves, which travel through the interstellar space and the air of the atmosphere. Radiant energy is converted into heat when it comes into contact with a material surface. If this surface absorbs 100 per cent of the impinging radiant energy it is known as a perfectly opaque body. Air absorbs very little radiant energy; water (*e.g.*, humidity in the air) absorbs much more. The human skin absorbs 97 per cent of the irradiation (infrared rays) that falls on it (Hardy and Muschenheim). It emits radiations of wavelengths varying from 50,000 to 200,000 A, with a maximum at 90,000 A (Hardy). These wavelengths are so far from those of visible light that the color of the skin (white or black) has no importance in this respect.

Radiation is proportional to the surface of the radiant body, to its power of emission, and to the difference between the absolute temperature of the radiant body raised to the fourth power and the absolute temperature of the coldest body receiving the radiation also raised to the fourth power.

The human body does not radiate heat to the surrounding air, but through the air to cold objects in the environment; *e.g.*, the walls, floor, ceiling, and furniture in a room, and through the windows to objects outside such as snow or ice. The essential factor in radiation is the difference in temperature between the bodies.

Thus if a subject is placed between a lighted stove and a cold wall, he will receive radiation from the hot stove and emit radiation to the cold wall. A perfect heating system heats the walls, ceiling, and floor of a room to the desired temperature.

Only 70 to 80 per cent of the body surface radiates heat, because certain parts, such as the axillae, the medial aspects of the thighs, etc., radiate to other parts of the body and not to objects in the environment. When many people are in the same room they irradiate each other, their body temperature rises, and discomfort is felt. "Vitiation" of the air has nothing to do with this process, but the increase in humidity of the atmosphere interferes with another mechanism of heat loss, *i.e.*, vaporization.

Convection. This consists in the transmission of heat in currents of liquids or gases resulting from differences in density or other causes. The air surrounding a radiant body is heated and rises; colder air replaces it, and thus currents are formed which carry away heat from the radiant body. The air between the layers of clothes, and between the meshes of the cloth out of which these are made, remains stagnant or circulates very slowly, so there is no loss of body heat by convection, and as air is a bad heat conductor it acts as an even more efficient insulator than clothes. More heat is lost by convection if air currents are artificially made by fans; loss of heat by evaporation can also be increased in this way. Convection increases with the speed of the air current up to 125 km. (78 miles) per hr.; a further increase in speed does not increase convection.

Evaporation. One liter of sweat absorbs 580 kg.-cal. on evaporation (pure water absorbs 539 kg.-cal.). Water evaporates on the skin and lung surfaces in direct proportion to the difference in temperature between the body and the environment and inversely to the percentage of humidity in the air. At temperatures between 18 and 30°C. (64 and 86°F.) the organism loses by evaporation from 22 to 27 per cent of the total heat loss. There are two types of evaporation on the skin, insensible perspiration and sweating.

Insensible perspiration consists in the evaporation of such a small amount of water that it vaporizes as soon as it is excreted. An adult man with a normal BMR loses 30 gm. of water per hour by this means; if the BMR rises, insensible perspiration increases and vice versa. Subjects without sweat glands lose approximately 18 gm. of water per hour by insensible perspiration.[1] Sanctorius (1614) was the first to measure insensible perspiration by placing the subject on a balance and noting the loss of weight, which is due mostly to the evaporation of water and only in small part to the difference in weight between CO_2 lost and oxygen absorbed.

Evaporation does not increase noticeably with an increase in environmental temperature up to 28 or 30°C. (81.4 or 86°F.). At this temperature there is a sudden increase due to sweat secretion, and at 35°C. (95°F.) nearly all the heat is eliminated by evaporation. At 37°C. (98.6°F.) heat cannot be eliminated from the organism by radiation; therefore evaporation accounts for all the heat lost. Heat is absorbed by the body from the environment when the outside temperature is above 37°C., but it is again eliminated by evaporation of sweat.

An optimum sensation of well-being is experienced with an environmental temperature around 20°C. (68°F.) and a relative humidity of 50 to 60 per cent. Evaporation diminishes as the humidity of the atmosphere increases. With a temperature of 37°C. and 100 per cent humidity, it would be impossible for the organism to lose heat either by radiation or evaporation; in this case the temperature of the skin rises above that of the environment and heat is thus eliminated by radiation but mainly by vaporization. Heat is tolerated better in a dry atmosphere than in a damp one; a subject in a warm and damp environment suffers discomfort, his temperature rises, and more serious effects may occur if the heat elimination is insufficient. This condition is observed in damp, hot valleys, near rivers, and in badly ventilated mines and workshops.

Man can withstand high temperatures in a dry atmosphere; *e.g.*, a temperature of 127°C. (260.6°F.) can be tolerated for 8 min. (Blagden), although this temperature is high enough to grill a steak or to bake bread or apples. In these conditions the organism must evaporate large quantities of sweat. Therefore an equivalent amount of water must be drunk and the body must be half naked or lightly clothed. If the atmosphere is saturated with humidity, a temperature of 48 or 50°C. (120°F.) cannot be tolerated for more than a few minutes. Subjects with congenital absence of the sweat glands

[1] RICHARDSON, H. B., *J. Biol. Chem.*, **67**, 397, 1926.

suffer considerably from heat in summer or when performing exercise; hyperthermia is easily provoked in them and is sometimes dangerous.

Heat is lost through the lungs, mostly by evaporation of water, and partly by convection. In certain animals (*e.g.*, the dog, which has sweat glands only on the pads of its paws) a rise in the temperature of the environment, or an increase in heat production due to strenuous exercise, causes what is known as thermic polypnea. The animal stretches itself against the ground (to increase the loss of heat by conduction), its breathing becomes rapid and shallow, and its tongue hangs out. The tongue is kept damp by an increased secretion of the salivary and buccal glands. Heat is thus lost by vaporization of water on the surface of the tongue. If tracheotomy is performed, thermic polypnea is much less efficient as a cooling mechanism. Polypnea is governed by impulses discharged from the nerve centers, owing to an increase in the temperature of the blood, and by reflexes arising in the skin.

Relative importance of the different ways of losing heat. The three principal ways of losing heat account for the elimination of 90 to 95 per cent of the total heat lost: (*a*) radiation, 55 per cent; (*b*) convection and conduction, 15 per cent; (*c*) evaporation through the skin and lung, 22 to 27 per cent. The remaining 5 to 10 per cent is used as follows: (*a*) about 60 kg.-cal. is used in warming the inspired air and is eliminated in the expired air: (*b*) 100 kg.-cal. is taken up by the elimination of CO_2 from the lungs; (*c*) 30 kg.-cal. is used to warm food and water ingested and is afterward eliminated in the feces and urine. Table 67, made up of data taken from Rubner, Martin, Du Bois, and others, summarizes the relative importance of the different ways of eliminating heat.

Table 67. Heat Elimination

Manner of elimination	*Daily heat loss*	
	kg.-cal.	%
Radiation, convection, and conduction	2100	68
Evaporation of water (skin and lungs)	810	26
Heating of inspired air	60	1.9
Elimination of CO_2 by the lungs	100	3.2
Urine and feces	30	0.9
Total	3100	100

There is not much change in the way heat is eliminated while the outside temperature varies from 15 to 28°C. (59 to 81.4°F.). Strenuous physical exercise produces a considerable change in this picture. Thus Du Bois and Hardy report an observation in which a subject at rest eliminated 66 per cent of the total heat by radiation, 15 per cent by convection, and 19 per cent by evaporation. Strenuous exercise caused heat production and elimination to be multiplied by 5; the amount of heat lost by radiation did not change, but heat loss by evaporation increased to such an extent that 75 per cent of the total heat was lost in this manner, and only 12 per cent by radiation and 13 per cent by convection. Rectal temperature rose from 37.5 to 38.8°C., and the temperature of the skin fell by 2°C., owing to the evaporation of sweat.

Relative importance of chemical and physical mechanisms for the regulation of body temperature. Body heat is lost by radiation and convection at low temperatures (up to 25.5°C., *i.e.*, 77.5°F.). Heat loss by evaporation increases rapidly from 29°C. (83.4°F.) up, and above 35°C. (95°F.) evaporation accounts for almost all the heat lost. In many species heat production (metabolic rate) increases at low temperatures and from 30°C. (85°F.) to 35°C. (95°F.) the metabolic rate may also increase.

When the environmental temperature falls, women lose about 10 per cent less heat than men. Perhaps this is due to the fact that they usually have more subcutaneous fat than men. The increase in the metabolic rate caused by low temperatures is also greater in women than in men. Moreover, women perspire less than men at the same environmental temperature, and their metabolic rate decreases at temperatures between 30 and 35°C. (Hardy and Du Bois).

Anatomic and physiologic factors in physical regulation of temperature. Several factors condition the loss of heat. Hair[1] and feathers in animals and clothes in man play an important part in controlling the loss of heat. They not only are poor heat conductors, but also enclose air, which is an even less efficient conductor of heat. When considering clothes as thermic

[1] If an animal is shaved or varnished it loses great quantities of heat and soon dies if it is placed in a cold environment.

insulators, the following factors should be taken into account: (*a*) area of the body covered; (*b*) nature, thickness, and color of the stuff used; (*c*) numbers of layers of clothes, because air between the layers is a very efficient insulator.

The skin and the poorly vascularized subcutaneous adipose tissue are poor heat conductors. Cutaneous circulation varies considerably in different circumstances. It plays an important part in the control of heat loss, because body heat is carried by the blood to the skin, where it can be eliminated. At an environmental temperature of 34°C. (93.2°F.) the skin may receive 12 per cent of the blood output of the heart. There is readjustment of the circulation in these conditions; when the skin vessels dilate, there is vasoconstriction of the splanchnic area and contraction of the spleen. The blood vessels of the skin are very sensitive to the effects of temperature. Heat causes cutaneous vasodilatation by (*a*) a direct action on the vasomotor centers; (*b*) vasomotor reflexes; (*c*) axon reflexes; (*d*) a direct effect on the blood vessels. Cold, on the contrary, causes cutaneous vasoconstriction. The skin becomes cold, the circulation is sluggish, and the blood in the cutaneous vessels becomes cyanotic. Nevertheless if the skin is rubbed with snow or an arm is submerged in freezing water, intense but transitory vasodilatation is observed, the skin becomes red and warm, and there is hyperalgesia.

An increase in the temperature of the environment produces the following effects: (*a*) the skin becomes red and warm; (*b*) the circulating blood volume increases, because water is reabsorbed from the tissue fluids in the skin, muscles, and liver, and because the spleen contracts and ejects stored blood; (*c*) if the temperature rises to 30°C. (86°F.) or more, the heart rate, and sometimes the systolic volume, increases; (*d*) respiratory frequency increases; (*e*) if there is hyperventilation, alkalosis is provoked, with transitory increase in the pH and decrease of ammonia in urine; (*f*) if the environmental temperature rises above 30 or 35°C. (86° or 95°F.), there is a slight increase in rectal temperature and heat production.

Man protects himself from heat by (*a*) cooling the atmosphere, or increasing the temperature gradient by cooling the surrounding structures; (*b*) decreasing the area of skin covered by clothes, and the thickness of the latter, choosing them of white or light color; (*c*) increasing the surface of the skin that can be used for radiation and convection; (*d*) cutaneous vasodilatation, which increases heat loss by radiation and evaporation; (*e*) increasing the evaporation of sweat by producing air currents with fans, to increase convection and evaporation; (*f*) diminishing the intake of food, especially of protein and fat. The heat of the sun is tolerated better by subjects covered by light clothes and a hat than by naked subjects. Clothes protect the body not only from cold, but also from excessive heat.

Man protects himself from cold by (*a*) covering a larger area of the body surface with several layers of thicker clothes, preferably of dark colors; (*b*) cutaneous vasoconstriction; (*c*) diminishing the surface of irradiation; (*d*) increasing heat production by exercise, high muscle tonus, and shivering; (*e*) increasing the caloric intake, especially in the form of protein and fat; (*f*) heating the environment (stoves, central heating, etc.).

Sweat Secretion

Sweat is a fluid excreted by the sweat glands in the skin. The sweat glands are highly developed in man and in the horse, but there are few or none in other species; thus the dog and cat have sweat glands only on the pads of their paws. Nevertheless the cat has been used quite as frequently as man or the horse in work done on the physiology of sweat secretion.

Sweat should be distinguished from insensible perspiration, which has been given this name because it is an imperceptible loss of water through the skin, even in subjects in whom the sweat glands are congenitally absent. At the rate of approximately 30 gm. per hr., between 600 and 800 gm. of water is evaporated by insensible perspiration every 24 hr., and this evaporation accounts for one-quarter of the heat lost by a resting subject. Insensible perspiration is greatest on the palms of the hands and the soles of the feet; next on the back of the hands, the neck, and the face; and least on the rest of the body surface.

Sweat glands. There are two types of sweat glands, according to Kuno:

1. *Eccrine glands*, distributed over the whole surface of the body, secrete a dilute fluid. There are from 2,000,000 to 3,000,000 of these glands. Placed on end, one after the other, they would extend over 2½ miles, and their aggregate mass is equivalent to

half that of one kidney. They are more numerous on the palms of the hands, the soles of the feet, the neck, and the trunk.
2. *Apocrine glands* are larger. They are found in the axillae, around the nipples, and on the mons veneris and labia. Their secretion has a characteristic odor.

The secretion of sweat is not a simple filtration of blood plasma through the glandular epithelium, because the pressure of sweat secretion (measured by a manometer occluding the glandular duct) can rise above the blood pressure (*e.g.*, to 250 mm. Hg). When the glands are active, circulatory, histologic, physical, and chemical phenomena typical of true secretion are observed. There is usually marked vasodilatation when the glands are secreting, but it is possible to dissociate the glandular and vascular responses. Thus secretion can be provoked by nerve stimulation in the sweat glands of a limb in which the circulation has been suppressed by ligatures or of one that has just been amputated. In certain circumstances sweat secretion occurs at the same time as vasoconstriction; in the cold sweat of intense emotion (anguish, fear) or in anoxia, the skin is pale. This type of sweating is more marked in the palms of the hands, the soles of the feet, and the forehead.

Sweat. The composition of sweat varies according to the place on the body surface from which it is collected, and the cause that has provoked its secretion. Sweat is a dilute watery solution; its specific gravity is 1.002 to 1.003, seldom higher. Its chemical composition[1] has been determined under different conditions (Table 68). The pH varies from 5 to 7.5. Usually it is on the acid side, especially when there is an abundant secretion due to heat. Sweat provoked by exercise is less acid than "heat" sweat; it has more ash and a higher concentration of organic substances. Chloride is eliminated as NaCl, in concentrations of 0.15 to 0.5 per cent. Nonprotein nitrogen eliminated by the sweat amounts to 0.071 gm. per day; it increases when there is retention of urea or nonprotein nitrogen in the blood.

A rise in body or environmental temperature causes the secretion of sweat to increase. Maximum rates of 1 and 2 liters per hr. have been observed, and strenuous exercise in the sun may cause the loss of 4 liters in 1 hr. Heavy physical labor in a hot, dry atmosphere may cause the secretion of 8 to 11 liters of sweat in 5 to 8 hr. of activity. In one subject the sweat eliminated in the course of 14 days amounted to 79 liters—more than the weight of the body. The excretion of such large quantities of sweat causes the loss of important amounts of water and salt; up to 10 gm. of NaCl can be lost in this way in 3 hr. If this happens the NaCl concentration in blood plasma and tissue fluids decreases, and the subject suffers from cramps, general malaise, insomnia, and in some cases fever. These disturbances are cured or prevented by drinking saline solution (0.25 to 1 per cent NaCl) instead of water, or by taking NaCl in tablets.

Table 68. Properties and Composition of Sweat

	Range	*Usual value*
Density	1.001–1.006	1.003
Freezing point, °C.	−0.13–−0.54	−0.24
pH	5–7.5	5.2 (heat) 6.6 (exercise)
Water, %	99.2–99.6	
Solids, mg. %	258–890	680
Organic substances, mg. %	30–290	
Ash, mg. %	144–566	
Chlorine, mg. %	70–346	180
Potassium, mg. %	....	17
Sodium, mg. %	75–250	150
Sulfate, mg. %	4–6	5
Total N, mg. %	34–160	
Nonprotein N, mg. %	23–94	42
Urea N, mg. %	17–38	26

Note: Lactic, formic, acetic, propionic, butyric, capronic, caprylic, and citric acids are also found.

The innervation of the sweat glands. The sweat glands are innervated by cholinergic fibers of the sympathetic nervous system but there are also some adrenergic fibers. Sweat secretion is obtained by stimulating the sympathetic, or nerves which contain sympathetic fibers (*e.g.*, the sciatic nerve), the dorsal or cervical spinal cord, the medulla, the hypothalamus, and to a lesser degree certain cortical areas. Stimulation of the sympathetic fibers that cause sweat secretion liberates acetylcholine, which passes into the sweat. Acetylcholine injected into the arm artery provokes marked

[1] Talbert, G. A., *J. A. M. A.*, **87**, 1829, 1926; *Am. J. Physiol.*, **81**, 74 and 81, 1927; Whitehouse, *Proc. Roy. Soc., London, s.B.*, **117**, 139, 1935; Couraud, J., thesis, Bordeaux, 1935.

vasodilatation and sweat secretion on the palm of the hand. Acetylcholine and pilocarpine stimulate the secretion of sweat; atropine inhibits it. Acetylcholine and pilocarpine act directly on the gland, even after it has been denervated, although several weeks or months after denervation the response is less marked.

An intravenous injection of adrenaline does not provoke sweat secretion, but an intradermal one provokes local sweat secretion in 84 per cent of the cases. Noradrenaline has the same effect in 74 per cent of the individuals. Drugs that inhibit the sympathetic, *e.g.*, dibenamine, suppress this local action of adrenaline.

The sympathetic nervous system is of fundamental importance in the regulation of heat loss by evaporation of sweat. If the temperature rises, sweat is secreted by all the sweat glands, except those in a denervated area. The nerve centers are very sensitive to variations in the temperature of the blood; thus, if the blood in the carotid arteries is warmed, sweat secretion is stimulated, although there has been no increase in rectal temperature.

Sweat secretion is stimulated by (*a*) an increase in the temperature of the environment, heavy clothing, hot baths, or high-frequency currents (diathermy); (*b*) physical exercise, which causes body temperature to rise and impulses to be discharged from the nerve centers; (*c*) psychic factors, as intense emotional states, fear, etc.; (*d*) stimulation of nerve centers by asphyxia or other causes; (*e*) sleep; (*f*) reflexes, *e.g.*, local warming of a limb, centripetal stimulation of the sciatic or the splanchnic nerves in man, certain gustatory stimuli, etc.

The principal nerve centers that control sweat secretion are situated in the hypothalamus (Karplus and Kreidl). Sweat secretion is provoked by stimulating the hypothalamus electrically or by heating it locally by means of a thermoelectric apparatus or of tubes through which hot water circulates; also by injecting pilocarpine into the lateral ventricle (Cushing). The spinal centers are also sensitive to heat, although not so much as the hypothalamus. For this reason, transverse section of the spinal cord does not suppress sweat secretion below the section, and all the glands in the body respond to adequate stimuli. Section of the dorsal (afferent) roots does not suppress sweat secretion, because the secretory fibers leave the spinal cord in the ventral roots. Complete extirpation of the spinal cord below the first thoracic segment, in a patient with a progressive glioblastoma, suppressed sweat secretion provoked by heating except in the head and neck, although the sweat glands responded to direct chemical stimulation with furmethide.[1]

Sweat secretion can be inhibited by local application of cold on the skin, *e.g.*, submerging a limb in a cold bath, or for a short time by drinking iced water. When a subject lies on one side of the body, sweat secretion diminishes on that side and increases on the opposite side.

Sweat secretion has been studied mainly in man, horse, and cat (the pads of the paws). Insensible perspiration is measured by recording the loss of weight of the subject, or by measuring the increase in weight of absorbent substances placed over a small area of skin and hermetically covered. Sweat is collected by means of absorbent pads or in a rubber glove. If paper impregnated with silver nitrate is placed over the skin, when the sweat secretion begins, the openings of the sweat glands leave an impression on the paper (Aubert). If the skin is dusted with talcum powder containing tartaric acid and blue litmus, over the area where sweating occurs the powder takes on a red color owing to the acidity of the sweat. Sweat secretion is provoked experimentally by heat, exercise, pilocarpine, or stimulation of nerves (sympathetic, sciatic, etc).

The Nervous System in the Regulation of Body Temperature

The mechanisms that regulate body temperature are integrated by the nervous system. The young of homoiothermic species that are born mature, *i.e.*, with a well-developed nervous system, having their eyes open, and walking and feeding themselves (*e.g.*, horses and cows), resist cold fairly well. On the other hand, the young of species that are born with an imperfectly developed nervous system, with their eyes closed, or with incomplete locomotion (*e.g.*, man, rat, pigeons), do not resist cold (Milne, Edwards, Pembrey).

Peripheral nerves. The following peripheral nerves take part in the regulation of temperature: (*a*) motor nerves, which stimulate movements and tone in muscles (there is a rapid fall in temperature in animals intoxicated with curare, which paralyzes the muscles, and in animals in

[1] MacCarty, C. S., G. M. Roth, and G. J. Thompson, *Proc. Staff Meet., Mayo Clin.*, 26, 113, 1951.

which the spinal motor centers have been destroyed); (*b*) vasomotor nerves, which constrict and dilate cutaneous nerves; (*c*) the nerves of the sweat glands. After bilateral removal of the whole sympathetic chain in cats, the animals have a normal temperature as long as they are kept in a warm room, but the response to cold is disturbed. There is no erection of hairs or cutaneous vasoconstriction, and in spite of their shivering at higher temperatures than the controls, their body temperature falls more easily than in normal animals. In a hot atmosphere their body temperature rises sooner than that of the controls.[1]

Cerebral cortex. The decorticate dog maintains a normal temperature and responds normally to heat and cold. Nevertheless shivering occurs sooner than in the controls when it is exposed to cold, and the body temperature falls easily; when it is exposed to heat, thermal polypnea appears later than in the controls. Removal of the frontal lobes provokes chronic disturbances in the vasomotor reactions of the skin in dogs and monkeys. Probably the cortex is more important in body-temperature regulation in man than in other species.[2]

Hypothalamus. The principal centers that integrate body-temperature regulation are situated in the hypothalamus. Section of the brain rostral to the hypothalamus provokes little or no change in body temperature, even when the striate (which was once considered the main center of temperature regulation) is removed. A transverse section of the brain immediately caudal to the hypothalamus causes serious disturbances in the regulation of body temperature.[3] Animals thus treated resemble poikilothermic animals, because their temperature falls rapidly if they are exposed to a temperature of 20°C., and it is necessary to keep them in a room at 30 to 35°C. to keep them alive. The hypothalamus is sensitive to temperature changes and provokes responses adequate to restore the normal body temperature. Thus heating the hypothalamus causes vasodilatation, sweating, and hyperpnea (Barbour),[1] while cooling it causes vasoconstriction and tremor.

Two areas have been differentiated by experiments in the hypothalamus. The rostral part of the hypothalamus integrates responses that cause loss of heat and prevent hyperthermia. This area is situated above and rostrally to the optic chiasma, under the anterior commissure (supraoptic and preoptic nuclei). Warming this area provokes vasodilatation, sweating, and hyperpnea in the cat. Destruction of this area brings about the loss of normal response to heat; there is no hyperpnea, and hyperthermia occurs when the animals are placed in a warm environment. Fatal hyperthermia has been observed in animals and man in cases of destructive lesions in this area.

The caudal part of the hypothalamus integrates the physiologic response to cold, which prevents the fall of body temperature. Bilateral destructive lesions of the caudal part of the lateral nuclei of the hypothalamus, provoked experimentally or observed in patients, provoke a decrease in BMR and subnormal temperature; on exposure to cold, vasoconstriction occurs, but there is no shivering. There are sympathetic centers in this area, and probably there are also centers that exert some influence on the thermal tonic contractions of striated muscles, perhaps through tectospinal and rubrospinal paths. The temperature-regulating impulses discharged from the hypothalamus stimulate medullary and spinal centers; they do not act directly on peripheral structures (see Chap. 84, Functional patterns integrated in the hypothalamus).

The spinal cord. A transverse section of the nerve centers anywhere between the superior colliculi and the lower segments of the cervical spinal cord converts a homoiothermic animal into a poikilothermic one, because of the separation of the spinal cord from the hypothalamic temperature-regulating centers.

In dogs, if the spinal cord is cut at the level of the first thoracic segment, heat regulation by sympathetic control (vasomotor nerves, etc.) is lost, but the dogs can maintain their body temperature in a cold environment, because the muscles of the neck and forelimb remain innervated; shivering limited to a restricted area can, therefore, be enough to maintain a normal

[1] Magoun, H. W., *et al.*, *J. Neurophysiol.*, **1**, 101, 1938.

body temperature. On the other hand, if the cervical and brachial plexuses are cut and the lumbosacral segments of the spinal cord are destroyed, the dogs cannot maintain a normal body temperature in a cold environment.[1] In man lesions of the cervical spinal cord usually provoke hyperthermia; complete section usually causes hypothermia,[2] but in some cases hyperthermia has been observed.[3]

Endocrine Regulation of Body Temperature

Thyroid. The thyroid gland shows signs of greater activity in winter than in summer. When an animal is taken from a warm to a cold environment, histologic signs of thyroid hyperactivity are observed. This does not take place if the hypophysis has been previously removed or the hypophyseal stalk has been cut.[4] It therefore seems that cold acts on the hypothalamus and provokes a discharge of impulses that increase the secretion of thyrotrophin from the anterior hypophysis, thus stimulating the thyroid.

Thyroidectomized animals have a cold skin, and frequently their temperature is subnormal. Their heat regulation is deficient; thus they react to the injection of pyrogenous vaccines with a less marked rise in body temperature than is seen in normal animals.

In hyperthyroidism the skin is usually warm, and the temperature is high but within the normal range. Hyperthermia is not usually observed because, although heat production is increased, heat loss increases sufficiently to maintain a normal temperature balance. Some hibernating animals can be awakened from the winter sleep by the injection of thyroxine, which increases their BMR and body temperature.

Adrenals. Injection of adrenaline or the sudden discharge of adrenaline from the adrenal medulla causes an increase in the metabolic rate and in some cases a rise in temperature. On cooling an animal, there is a discharge of adrenaline, which increases heat production (Cannon *et al.*). Adrenalectomized animals do not resist cold well (Cannon, Marval), but this is due mainly to corticoadrenal insufficiency, not to the lack of adrenaline secretion. Corticoadrenal treatment restores the normal response to cold in these animals.

Hypophysis. Anterior hypophyseal insufficiency causes a decrease in the resistance to cold and a definite fall in the BMR (25 to 40 per cent, according to the species). In this condition there is a certain degree of adrenal and thyroid insufficiency, which adds to the effect produced by the absence of hypophyseal hormones. The anterior hypophysis exerts a continuous indirect action on heat production by maintaining a normal level of thyroid and corticoadrenal functions.

FEVER

The rise in temperature observed in fever is due to a considerable increase in heat production, which is frequently doubled and sometimes reaches five times the BMR, as occurs in an attack of malaria or similar conditions. In the first stage there is shivering, cutaneous vasoconstriction, paleness, goose flesh, and a sensation of cold. Heat production is increased (shivering) and heat loss is decreased (cutaneous vasoconstriction); therefore the body temperature increases because more heat is produced than is eliminated. When the temperature reaches its peak, the skin becomes warm because of cutaneous vasodilatation and heat loss increases. If the fever recedes (crisis), there is muscular relaxation and abundant sweating. Heat loss then predominates over heat production and the temperature falls.

An increase of body temperature up to 40°C. (104°F.) is frequently observed, but a rise above this temperature seldom occurs, as if there were mechanisms that controlled these higher rises.

When there is continuous fever, heat control is adjusted to maintain a high temperature. The patient sweats and the cutaneous blood vessels dilate if he is covered to excess or submerged in a warm bath; on the contrary, he shivers, the cutaneous blood vessels contract, and he has goose flesh if he is submerged in a cold bath. Heat control is not so firm in these conditions as in normal subjects; *e.g.*, in a cold bath the patient's body temperature falls more easily than that of a healthy person. Also exercise easily causes an increase in body temperature in febrile subjects (tuberculosis, convalescence of typhoid fever, etc.).

The following signs and symptoms are present in fever: malaise, mental torpor, headache, depression, delirium, loss of appetite, constipation. They dis-

[1] Chatonnet, J., *J. de physiol et de path gén.*, **43**, 678, 1951.

appear when the temperature falls as a result of treatment with antipyretic drugs or cold baths.

The metabolic rate increases in fever in proportion to the increase in temperature; there is approximately a 13 per cent rise for every degree centigrade of temperature above the normal. The pulse rate increases. The blood pressure rises and remains high if the temperature increases suddenly, but returns to normal when there is a stable temperature, even if there is fever. Pulmonary ventilation increases as the temperature rises.

Protein breakdown increases in fever; therefore there is a greater excretion of nitrogen, urea, and creatinine. The minimum protein requirement to maintain nitrogen equilibrium is higher than in normal subjects, in spite of the fact that protein does not account for more than 20 per cent of the total calories spent by a fasting patient with fever. The sharp fall in temperature characteristic of the crisis is accompanied by polyuria and the excretion of a large quantity of urea. Fat and carbohydrate are consumed in larger amounts during fever. If sufficient carbohydrate is not ingested, there is a tendency to ketosis and acidosis.

During fever the blood becomes concentrated, blood chlorides decrease, and little or no chloride is excreted in the urine. Ingested chloride is retained in great part in the tissue fluids. When the temperature drops, there is polyuria and the retained chloride is excreted.

Fever is probably due to disturbances in the hypothalamic heat-regulating centers. Many antipyretic drugs produce their effect by acting on the hypothalamus.

Treatment by hyperthermia. Certain diseases (rheumatism, gonorrhea, syphilis, mental diseases, etc.) are treated by provoking hyperthermia in the patient. Hyperthermia can be produced by (*a*) infection with *Plasmodium malariae;* (*b*) bacterial vaccines; (*c*) high-frequency currents (diathermy); (*d*) specially constructed ovens. Temperatures of 39 and 40°C. (102 and 104°F.) and pulse rates of 160 or more are provoked by these means. A severe strain is therefore placed on the organism, and the patient should be carefully watched during the whole process.

ACCIDENTS DUE TO COLD AND HEAT

Exposure to cold after the response of the organism has been exhausted produces weakness, sleep, torpor, coma, and death. If the body temperature falls to between 20 and 24°C. (66 and 75.2°F.) the subject seldom recovers, but if the temperature has fallen only to 27 or 29°C. (80.6 or 84.2°F.) and the subject is adequately treated by being rapidly warmed in a hot bath, recovery frequently occurs. Local freezing of tissues causes disturbances in local circulation, with the eventual mortification and destruction of the tissues.

Excessive heat can overcome the resistance of the organism with serious and even fatal results (heat stroke). Sweating diminishes; the metabolic rate, temperature, and pulse rate increase; there is hyperpnea, exhaustion, malaise, and irritability or somnolence. The mechanisms that regulate body temperature do not function, and the nerve centers suffer from the increase in temperature. The respiratory center of mammals ceases to function soon after the temperature rises to 44 or 45°C. (111.3 or 113°F.). Death is due to circulatory collapse. Sometimes convulsions are observed; in other cases the subject becomes comatose in the final stages. A few cases of survival of patients having had a temperature of 45°C. (113°F.) have been reported.

TEMPERATURE REGULATION AND CLIMATE

Deficiency in heat loss produces discomfort. The principal factors which regulate heat loss through the skin and which depend on climate are (*a*) the difference in temperature between the skin and the environment; (*b*) the humidity of the atmosphere; (*c*) the movement of the air surrounding the individual. Hill[1] has suggested the use of the katathermometer. The thermometer is warmed and the speed at which it cools is determined; then it is again warmed, the bulb is surrounded by damp cotton, and the speed of cooling is again determined. The first curve corresponds to heat lost by radiation, and the second to that lost by evaporation. The influence of the humidity of the atmosphere on heat loss can thus be measured.

CHAPTER 49

Vitamins

VITAMINS ARE ORGANIC substances which the tissues cannot synthesize in sufficient quantities by metabolic processes. They must be found in food, preformed or as "provitamins" which are converted into vitamins, *e.g.*, carotenes are transformed into vitamin A. Some vitamins are produced by bacteria in the digestive tract, *e.g.*, vitamin K, but not in sufficient amounts to satisfy the needs of the body. Only very small amounts of vitamins are needed for normal nutrition, but these are indispensable, otherwise a specific deficiency disease appears, *e.g.*, rickets, beriberi, scurvy, etc. Several vitamins form part of coenzymes in the enzymatic systems of fundamental metabolic processes.

The term "vitamin" was proposed in 1912 by Funk, who believed there was one amine indispensable for life. Later work showed that there were several indispensable substances and that most of them were not amines.

Long before vitamins were discovered, the disturbances caused by their deficiency had been described, and methods of curing these diseases by giving certain foods, which are now known to contain the missing vitamin, had been discovered. The effect of the complete lack of a vitamin is known as "avitaminosis" and that of an insufficient amount as "hypovitaminosis." In many cases weeks or even months pass before the signs of deficiency are evident, because the organism stores vitamins and these stores take time to be exhausted. In the first stages of the disease it is easy to obtain a complete cure very rapidly by the administration of the missing vitamin, but after a time it is more difficult to restore the normal condition. Sometimes a complete cure is not obtained, or the process may have become irreversible. Slight insufficiencies are not always easy to recognize, and this fact may have social consequences because the health of large numbers of the community may be impaired.

Vitamins are unstable; therefore they are easily destroyed by oxidation in the process of preparing foods and in stored foodstuffs. They are preserved by quickly drying the foods at low temperature and by storing them dry in an atmosphere free from oxygen. Many of the vitamins are destroyed by heat, especially in an alkaline medium. Food that contains them should therefore not be submitted to prolonged cooking at temperatures above 100°C.

Vitamins have not only been isolated in the pure state but also prepared by synthesis. Thus large quantities, easy to preserve, can be obtained at low cost for therapeutic, preventive, and experimental uses. This has made possible the observation of the effects on the organism of extraordinarily large amounts of vitamins. In some cases disturbances known as hypervitaminoses have been seen. Hypervitaminoses never occur spontaneously in man; they are diseases provoked in laboratory animals by repeated administration of excessively large doses of one or another of the vitamins. The condition may become severe and the animals may die if the treatment is sufficiently prolonged. In man a few cases of hypervitaminosis D have been reported as a result of excessive doses of the antirachitic vitamin taken over long periods without adequate supervision.

Vitamins are not only indispensable to higher animals; they are also necessary for growth and development of bacteria and yeasts. A vitamin that is essential for one species, however, is not necessarily indispensable to another. Some of the vitamins (thiamine, riboflavin, niacin) are synthesized by the bacteria in the intestine, which are thus a source of vitamins partially satisfying the requirements of the host. Certain

intestinal disinfectants, such as sulfamides or antibiotics, diminish the production of these vitamins by inhibiting bacterial growth. The same effect is observed in certain intestinal diseases.

The activity of vitamins and their concentration in foods is estimated by physical, chemical, or biological methods. The latter consist in the experimental production of the required avitaminosis in animals of a species susceptible to the deficiency, which are then treated with different foodstuffs with the object of observing the therapeutic effects. Recently microbiological methods, *i.e.*, the use of bacteria, have been more frequently employed in the assay of vitamins. Controls made by treating human cases should be used whenever this is possible.

Nomenclature. The term "provitamin" is used for substances that are not vitamins but can be converted into vitamins. When first discovered, the vitamins were distinguished from each other by letters, but later, as their chemical nature became known, the appropriate chemical names came into use. Nevertheless conventional names or letters are commonly used, because they are easy to remember. Up to now over twenty vitamins have been described. Many of them are indispensable for growth of bacteria or yeasts; here only those of importance in human nutrition will be considered. A primitive classification of vitamins divided them into fat-soluble and water-soluble vitamins, because they were first found dissolved in natural fats or extracted by water from different foodstuffs. Some of the vitamins form groups of chemically related substances, with similar biological activity.

Group A: A_1, axerophthol; antixerophthalmic.
A_2, similar to A_1.

Group B: B_1, thiamine or aneurine, antineuritic or antiberiberi.
B_2, riboflavin or lactoflavin.
B_6, pyridoxin, antidermatitis factor in the rat.
B_{12}, extrinsic antianemic factor.
Folic acid, pteroylglutamic acid, antianemic.
Nicotinic acid (niacin), nicotinic amide (niacinamide), P-P or pellagra-preventing factor.
Human requirements of some important vitamins are not well known, *i.e.*, pantothenic acid, biotin, inositol, paraminobenzoic acid (PABA), streptogenin.

Vitamin C: Ascorbic acid, antiscorbutic.

Group D: D_2, calciferol (ergocalciferol) derived from ergosterol by irradiation; antirachitic.
D_3, (cholecalciferol), D_4, D_5, and D_6, similar to D_2.

Group E: α, β, and γ tocopherols; antisterility factor; human requirement unknown.

Group K: K and K_2, coagulation vitamin; antihemorrhagic, stimulates formation of prothrombin.

Vitamin P: Citrin or hesperidin; associated with ascorbic acid in maintaining capillary-wall resistance.

The human requirement of vitamins increases in the following circumstances: (*a*) increase in metabolic rate, *e.g.*, manual labor, high BMR; (*b*) increase in catabolism, as in hyperthyroidism and diabetes; (*c*) pregnancy and lactation; (*d*) growth; (*e*) deficient absorption, *e.g.*, alcoholism; (*f*) certain chronic diseases, convalescence, and healing of wounds.

Ingestion, absorption, storage, or transformation of vitamins can be disturbed in several pathologic conditions. Ingestion and absorption are hindered in diseases of the mouth, stomach, and intestines. Absorption of water-soluble vitamins is disturbed by gastric achylia and alcoholism. Absorption of fat-soluble vitamins is disturbed when there is obstruction of the bile ducts, or functional insufficiency of the intestinal mucosa, or commonly when cathartics such as mineral oil are administered over a period of time. Storage and transformation of vitamins A, D, K, and B are deficient when the liver cells are damaged. In these cases the deficiency is said to be secondary, since it is not due to a primary deficiency of the vitamin in the diet.

Antivitamins. Certain enzymes in foods destroy some of the vitamins. There are also substances with a chemical structure similar to the vitamins which cause avitaminosis by the mechanism of substrate competition,[1] similar to the mechanism by which carbon monoxide competes with oxygen for hemoglobin. These so-called "antivitamins" will be considered when dealing with each vitamin in particular.

[1] Woolley, D. W., *Physiol. Rev.*, **27**, 308, 1947; *Ann. New York Acad. Sc.*, **52**, 1197, 1950.

VITAMIN A

Vitamin A is known as the "antixerophthalmic" vitamin, because its deficiency causes a disease in the eye called xerophthalmia. Its chemical structure is known and it has been prepared by synthesis, but there is at least one other substance (vitamin A_2) and perhaps several, of unknown chemical structure, which have the activity of vitamin A.

Avitaminosis and Hypovitaminosis

Vitamin A maintains epithelial tissues in normal condition, thus protecting them from physical or bacterial aggression. Deficiency of vitamin A causes atrophy of epithelial tissues, followed by proliferation of the basal cells, with abnormal formation of large numbers of cornified cells (Wolbach).

Vitamin A deficiency in man. The following signs and symptoms are observed in man when there is deficiency of vitamin A:

1. *Xerophthalmia.* There is thickening of the con junctiva, which loses its transparency; lachrymal secretion diminishes, the conjunctiva becomes dry, and the conjunctival folliculi are hypertrophied, especially on the lower lid (follicular conjunctivitis).
2. *Keratomalacia.* In advanced stages of severe cases the cornea is thickened and ulcerated, and sometimes the eyeball is perforated.
3. *Papular eruption in the hair follicles with keratosis* of the area around them gives the skin the aspect of goose flesh. This is especially marked on the arms and legs.
4. *Cutaneous xerosis, i.e.,* dry, scaly skin, with or without follicular keratosis.
5. *Night blindness* (nyctalopia), consisting in failure of vision in twilight or at night, is frequently found in undernourished communities. It is due to vitamin A deficiency. The vitamin bound to a protein forms the visual purple (rhodopsin) in the retina. Exposure to light converts rhodopsin into retinene or xanthopsin (visual yellow), which is an aldehyde of vitamin A bound to a protein. Light acting on visual purple stimulates the optic nerve endings and sends impulses along the nerves. In the dark, retinene is reconverted into visual purple. If there is vitamin A deficiency, the process of visual purple regeneration is retarded. Administration of vitamin A rapidly restores the normal condition (see Chap. 78). Hypovitaminosis A can be detected by measuring the time of adaptation to darkness on passing from intense to dim light; this time is prolonged in cases of vitamin A deficiency. The test has no significance in isolated cases, but it is useful in the statistical determination of vitamin A deficiency in a community, especially when treatment with vi amin A accelerates dark adaptation, while individuals not treated show no change.
6. *Susceptibility to infections.* The epithelia of the digestive, respiratory, and genitourinary tracts become dry and cornified and are easily infected. Infections are frequently observed in the middle ear, eyes, nasal sinuses, bronchi, and the genitourinary tract. Treatment with vitamin A rapidly clears up the infection, a fact that has made some workers refer to this vitamin as the anti-infectious vitamin. If there is no deficiency, vitamin A even in large doses has no effect on the course of infections.

Experimental avitaminosis A. The following symptoms are observed in laboratory animals fed on a diet free from vitamin A:

1. *Loss of weight,* although the bones do not cease to grow.
2. *Ophthalmia.* The conjunctiva is dry and thickened and later becomes infected. The eyelids are red and swollen.
3. *Cornification of epithelia* of the respiratory, digestive, and urinary tracts, the vagina, and numerous glandular ducts. The epithelial linings are formed by flat, stratified cells, which become cornified, dry, and desquamatory.
4. *Suscebtibility to infections.*
5. *Nephrolithiasis.* Renal stones are frequently formed by desquamation of the keratinized epithelium of the renal pelvis.
6. *Degenerative changes in spinal and cranial nerves,* caused by compression of these nerves at their point of emergence from the cranium or spinal cord by thickening of the bone and narrowing of the foramina through which the nerves pass. This is due to excessive activity of the osteoblasts and insufficient activity of the osteoclasts.[1] There is insufficient evidence of its occurrence in man.

[1] Mellanby, E., *Proc. Roy. Soc., London, s.B.*, **132**, 28, 1944.

Hypovitaminosis A is diagnosed either by measuring adaptation to darkness (see above) or by estimating the concentration of vitamin A in the blood. It is treated by giving 25,000 international units (IU) of vitamin A daily.
